Re: TCCHINOOK (06)-1 – Conduct of Canadian AABM Fisheries

The attached working group report on the October 19, 2005 assignment given to the Chinook Technical Committee by the Pacific Salmon Commission regarding the conduct of Canadian AABM fisheries has been received by the Commission's Chinook Interface Group (CIG). The report will be presented to the Commission for consideration at its Executive Meeting scheduled for October 17-19.

PSC Chinook Technical Committee

TO: Pacific Salmon Commission

FROM: Rick McNicol, Scott McPherson, and Dell Simmons, Co-Chairs, Chinook Technical Committee

DATE: July 28, 2006

SUBJECT: Final Report on the October 19, 2005 Assignment Re: Conduct of Canadian AABM Fisheries

The attached report addresses the ten tasks assigned to the CTC by the Pacific Salmon Commission on October 19, 2005 at the request of the Chinook Interface Group. The report was produced by a subgroup of the Chinook Technical Committee appointed by the Co-Chairs. Included in the report are the data and analyses associated with these tasks, as well as specific recommendations to the Commission based on the results and findings in the report.

EXECUTIVE SUMMARY	v
INTRODUCTION	1
ASSIGNMENTS	2
1. At the discretion of the co-chairs, assign a workgroup to have primary responsibility for completion of these tasks;	2
2. View the presentation of "Chinook and Coho Salmon Genetic Stock Identification" as catalogued on the PSC website (from June 2004), and other related presentations by DFO staff (e.g., Wilf Luedke to the Southern Panel, February 2005; Rick McNicol to the Northwest Power and Conservation Council, July 2005);	2
3. Review management plans and supporting information and provide a synopsis of management objectives and actions with respect to specific stock concerns for the NBC and WCVI AABM fisheries from 1995 through 2004. Provide an assessment of the degree to which those objectives were achieved and do so in terms of harvests and of exploitation rates on the stocks of concern;	3
4. For the years 1979-1998, and 1999-2004 provide effort and catch data by month (or other appropriate time period) by management area (or sub-area as appropriate) for the NBC and WCVI AABM fisheries;	13
5. To the extent possible, compare stock composition data available from coded wire tag recoveries and from the CTC Chinook model for the years 2000-2004 to the GSI data assembled by Canada to facilitate recent management of the NBC and WCVI fisheries.	22
6. Specify the sampling levels and procedures employed in each fishery and time period for CWT and GSI data for the years 1985-2004;	36
7. For those stocks for which analysis is available, update through 2003, with the addition of 2004 when data becomes available, the tables listed in Appendix G of CTC (2004). For all stocks compare average figures for appropriate prior years to average figures for those years (e.g., 1999-2004) for which specific stock concerns influenced the conduct of the NBC and/or WCVI fisheries;	55
8. Provide annual stock compositions through 2004 for the WCVI and NBC fisheries as in Appendix I of TCCHINOOK(04)-4, again with average figures calculated for appropriate prior years compared with average figures for those years for which specific stock concerns influenced the conduct of the NBC and WCVI fisheries;	70
9. For the NBC and WCVI fisheries, provide the CTC's assessment of the GSI data that supports the presentations referenced in 2 above and the stock-specific management plans, and detail how that data may be utilized in advancing our understanding of stock composition in those fisheries;	91
10. After the tasks listed above have been completed, outline, in a separate document if necessary, technical difficulties for implementation of the agreed AABM fishery regimes that may be created by fishery patterns that change (possibly in-season) in order to alter the exploitation rates on specific stocks.	

Include any recommendations for monitoring programs and for analytical methods to estimate stock-specific impacts (across the range of stocks in an AABM fishery) that may result from such alteration in the conduct of a fishery. ..	98
Analysis 1: A model-based method to analyze effects of changes in the timing of catch on stock composition.....	100
Analysis 2: Changes in Coded Wire Tag Concentration Indices for Stocks in Five Ocean Fisheries for 1979-2004.....	111

EXECUTIVE SUMMARY

On October 19, 2005 the Pacific Salmon Commission, at the request of the Chinook Interface Group (CIG), asked the Chinook Technical Committee (CTC) to investigate the effects of changes made to the conduct and monitoring of the West Coast Vancouver Island (WCVI) and Northern British Columbia (NBC) troll fisheries in recent years. The request consisted of ten assignments. The results are summarized below.

Assignment 1. At the discretion of the co-chairs, assign a workgroup to have primary responsibility for completion of these tasks;

A workgroup was formed during a scheduled full CTC meeting October 24-28, 2005 to address the assignments from the CIG (referred to as the Workgroup in this report).

Assignment 2. View the presentation of "Chinook and Coho Salmon Genetic Stock Identification" as catalogued on the PSC website (from June 2004), and other related presentations by DFO staff (e.g., Wilf Luedke to the Southern Panel, February 2005; Rick McNicol to the Northwest Power and Conservation Council, July 2005);

The members of the Workgroup have completed this assignment. During the course of this review errors were found in the approach used to estimate stock composition for the WCVI troll fishery. The errors were corrected to the extent possible given the available data for the 2004 accounting year, and corrected stock composition estimates for the WCVI fishery are provided. No such problems were found in the approach used in the NBC troll and QCI sport fisheries.

Assignment 3. Review management plans and supporting information and provide a synopsis of management objectives and actions with respect to specific stock concerns for the NBC and WCVI Aggregate Abundance Based Management (AABM) fisheries from 1995 through 2004. Provide an assessment of the degree to which those objectives were achieved and do so in terms of harvests and of exploitation rates on the stocks of concern;

The Workgroup collated and summarized the management objectives and regulatory measures implemented for the WCVI and NBC AABM fisheries. NBC AABM fishery management objectives for WCVI Chinook were attained for all years with the exception of 2003. For the WCVI AABM fishery, management objectives were achieved for WCVI Chinook and Thompson Coho in all years. However, impacts on Lower Georgia Strait Chinook were not reduced. Changes in WCVI troll impacts on Fraser Early Chinook could not be assessed.

Assignment 4. For the years 1979-1998, and 1999-2004 provide effort and catch data by month (or other appropriate time period) by management area (or sub-area as appropriate) for the NBC and WCVI AABM fisheries;

Catch and effort data are summarized by month in Tables 4-1 through 4-8. The Workgroup concluded that the temporal pattern of fishing in the NBC troll fishery has not changed as much as the pattern observed in the WCVI troll fishery. In the WCVI troll fishery, from 1999 through 2004, over 90% of the catch in the WCVI troll fishery was taken from September through May of the following year. From 1985 through 1995, almost 90% of the catch was taken in June through August of the same calendar year. During the 1979-1982 PSC Chinook model base period approximately 60% of the WCVI troll catch occurred during June through August.

The temporal distribution of the catch within calendar years for three different time periods is presented for WCVI troll and NBC troll below.

Table Exec. 1. Temporal distribution of the Chinook catch in the WCVI and NBC troll fisheries.

Fishery	Years	March-May	June-August	September-December ^a
NBC Troll	1979-1982	12.6%	71.6%	15.8%
	1985-1995	0.4%	89.4%	10.3%
	1999-2004	20.5%	65.2%	14.3%
WCVI Troll	1979-1982	28.2%	57.6%	14.3%
	1985-1995	2.4%	89.0%	8.6%
	1999-2004	58.3%	8.6%	33.1%

* Includes catch from January and February; see Table 4-1 to 4-4 for details.

Assignment 5. To the extent possible, compare stock composition data available from coded wire tag recoveries and from the CTC Chinook model for the years 2000-2004 to the GSI data assembled by Canada to facilitate recent management of the NBC and WCVI fisheries.

The Workgroup concluded that a useful comparison of stock composition estimates based on Coded Wire Tag (CWT) recoveries, the CTC Model, and Genetic Stock Identification (GSI) data could not be made. The available GSI data and PSC model estimates of stock composition for both AABM fisheries are presented in sections 5 and 8, respectively, of the main body of the report. Due to the general lack of representation of wild stocks, and in many cases, the lack of complete representation of hatchery stocks, in the CWT database, stock composition in these fisheries cannot be estimated using CWT recovery data alone.

Assignment 6. Specify the sampling levels and procedures employed in each fishery and time period for CWT and GSI data for the years 1985-2004;

CWT—Both the WCVI and NBC troll fisheries have met or exceeded a sampling level of 20% of the annual Chinook landed catch in all but one year from 1985-2004 (Figures 6-1 and 6-2). However, there were sampling periods within a year when less than 20% of the catch was sampled. Sport expansions for both fisheries are based on awareness factors that are derived from creel observations, voluntary head returns, and estimated

catches; at times these awareness factors are based on data gathered outside the specific fishery of interest. The Workgroup notes that direct sampling of the heads in Canadian sport fisheries would likely increase the accuracy and precision of CWT recovery data.

GSI—The NBC troll fishery was sampled in a representative manner from 2002-2005 to estimate: 1) the stock composition of Chinook in landed catch when fisheries were open and 2) the stock composition of available Chinook when fisheries were not open (samples obtained by test fishing). The sampling design provides annual estimates of stock composition of landed catch and temporal estimates of stock composition throughout the year. Sample sizes were sufficient to estimate contributions of stocks or stock groups that comprised 5% or more of the annual catch, with reasonable precision (see Tables 5-1A and 5-1B). The NBC AABM sport fishery was sampled in a representative manner from 2003-2005. The overall precision of the estimates is slightly less than that for the troll fishery. Estimates by month are less precise, and likely represent trends for major contributing stocks only.

The WCVI troll fishery GSI sampling was only applied to unclipped fish (2004 and 2005 accounting years). Upon detailed examination of the 2004 year, the Workgroup concluded that this approach, in conjunction with other errors, led to an incorrect estimation of the stock composition of the total catch that year. The Workgroup recommends that if future GSI work in WCVI fisheries is undertaken, that representative GSI sampling be done without regard to clip status. For both fisheries sample sizes taken would not be expected to provide reliable estimates of the contribution of stocks that comprise a small proportion of the catch.

Assignment 7. For those stocks for which analysis is available, update through 2003, with the addition of 2004 when data becomes available, the tables listed in Appendix G of CTC (2004). For all stocks compare average figures for appropriate prior years to average figures for those years (e.g., 1999-2004) for which specific stock concerns influenced the conduct of the NBC and/or WCVI fisheries;

The Workgroup updated the Appendix G tables through 2004. The WCVI AABM fisheries impacts are summarized below:

Table Exec 2. Summary of estimated changes of impacts of the WCVI AABM fisheries (troll and sport) on Chinook exploitation rate indicator stocks from 1979 to 2004.

Stock Complex	Summary Comments
Alaskan	Not significantly impacted.
North Central BC (Kitsumkalum)	Not significantly impacted.
WCVI (Robertson Creek)	The proportion of the total run accounted for by the WCVI AABM fisheries in 2002-2004 (2.7%) is less than 40% of the 1979-1982 average of 7%. The proportion of the total run taken by the WCVI troll fishery from 1979-1982 of 6.5% decreased to 0.2% from 2002-2004, about 3% of the base level.
Upper Georgia Strait (Quinsam Fall)	Historic impacts average less than 1%. No impacts observed in recent years.
Lower Georgia Strait (Puntledge, Cowichan, Big Qualicum)	Impacts observed in 2002-2004 were about the same as those in 1979-1982, for Puntledge and Big Qualicum stocks. Impacts on the Cowichan fall stock has tripled in 2002-2004, compared to 1985-1995.
Fraser Early (none)	No information

Fraser Late (Chilliwack)	No base period information is available. Impacts in 2002-2004 average 57% of the rates seen from 1985-1995.
Puget Sound Spring Chinook (Nooksack Fingerling, Nooksack Yearling, Skagit Fingerling, Skagit Yearling, White River Yearling)	Base period data are not available for these stocks and a complete time series in recent years is not available for Nooksack Yearlings and White Yearlings. The average proportion of the total run accounted for by reported catch in 2002-2004 exceeds the levels observed in prior years in 5 of 6 cases for Nooksack Fingerlings, 5 of 5 cases for Skagit Fingerlings, and 11 of 11 cases for Skagit Yearlings.
North Puget Sound Fall (Skagit Summer, Stillaguamish Fingerling, Nisqually Fingerling, Samish Fingerling)	Base period data are not available for this stock group. For most stocks, the proportion of the run taken by the fishery has not changed since the mid 1980s.
South Puget Sound Fall (SPS Fall Fingerlings, SPS Fall Yearling)	This stock group shows little change in the proportion of the run taken in 2002-2004 compared to the base period or other time periods.
Hood Canal (George Adams)	This stock group shows little change in the proportion of the run taken in 2002/03 compared to the base period or other time periods.
Washington Coastal Fall (Hoko, Sooes, Queets)	Historically, the reported catch by this fishery accounted for approximately 10% of the run. Impacts have been substantially reduced since 1999. In this stock complex, base period data are only available for the Queets. The proportion of the Queets run accounted for by the WCVI AABM fishery has been reduced from about 12% in the base period to about 1% in 2002-2004.
Willamette Spring	The reported catch by this fishery accounted for approximately 4% of the run during the base period. Impacts observed in 2002-2004 are about 3%. Impacts from 1985-1998 were about 2%.
Columbia River Summer	The reported catch by this fishery during the base period accounted for about 17% of the run. Impacts observed since 2001 have been substantially higher than levels observed from 1994-2000. In 2002-2004, the 14% of the run accounted for by the WCVI AABM fisheries was about 85% of the 1979-1982 base period levels.
Columbia River Tule (Cowlitz, Spring Creek, Lower River Hatchery)	The reported catch by this fishery accounted for approximately 16%-25% for these three stock groups prior to 1985. Impacts were reduced in response to PST regimes from the mid-1980s to late 1990s. Impacts observed in 2002-2004 were above the levels observed since 1985 and range from 59% to 95% of 1979-1982 base period averages, for these three stocks.
Lewis River Fall	The reported catch by this fishery accounted for about 8% of the run during the base period. Average impacts since then have been similar, about 7% from 1985-1995 and about 8% from 2002-2004. Impacts were estimated at 0% from 1996-2000.
Columbia River Bright	The reported catch by this fishery accounted for about 7% of the run in 1979-1982 but increased to an average of about 9% from 1985-1995. Impacts have been substantially reduced under the PST since the mid 1990s and were estimated to average about 2% in 2002-2004.
Snake River Fall	CWT data for this stock are very limited. Average impacts of 2.8% in 2003-2004 were about one-fifth of those observed from 1988-1994.
Salmon River Fall (Oregon Coast)	The reported catch by this fishery accounted for about 6% of the run during the base period and the average remained relatively unchanged for the period of 1985-1995. Average impacts were reduced to less than 1% since 1995 with no year since exceeding 2%.

The NBC impacts are summarized below:

Table Exec. 3. Summary of estimated changes of impacts of the NBC AABM troll fishery on Chinook exploitation rate indicator stocks from 1979 to 2004.

Stock Complex	Summary Comments
Alaskan	No base period data is available. Historic impacts average less than 1%.
North Central BC (Kitsumkalum)	No base period data is available. Impacts averaged about 8% of the run from 1985-1995 and impacts in 2002-2004 averaged about 3%.
WCVI (Robertson Creek)	The proportion of the run accounted for in recent years (1.8%) is less than one-sixth of that observed during the base period (about 11%).
Upper Georgia Strait (Quinsam Fall)	This fishery accounted for over 10% of the impacts to this stock in the base period. Impacts since 1999 have averaged less than 1%.
Lower Georgia Strait (Puntledge, Cowichan, Big Qualicum)	Impacts have decreased since the base period, and remain relatively small (about 2% or less).
Fraser Early (none)	No information
Fraser Late (Chilliwack)	No base period information is available. Impacts have consistently been < 1% since 1985.

Puget Sound Spring Chinook (Nooksack Fingerling, Nooksack Yearling, Skagit Fingerling, Skagit Yearling, White River Yearling)	The proportion of the run accounted for by reported catch in this fishery has remained unchanged under PST management. The impact on these stocks is very small (<1%).
North Puget Sound Fall (Skagit Summer, Stillaguamish Fingerling, Nisqually Fingerling, Samish Fingerling)	The impact of the fishery on these stocks is small, but has increased slightly since 1999 for the Skagit Summers, averaging about 2% of the run from 2002-2004.
South Puget Sound Fall (SPS Fall Fingerlings, SPS Fall Yearling)	Impacts on this stock group have increased in 2002-2004 compared to the base period and the pre 2002 periods, but remain very small (<1%)
Hood Canal (George Adams)	Impacts remain very small (<1%)
Washington Coastal Fall (Hoko, Sooes, Queets)	The reported catch by this fishery accounted for about 18% of the Queets run in the base period and about 12% from 1985-1998, but decreased to about 6% from 1999-2004.
Willamette Spring	The reported catch by this fishery accounted for approximately 10% of the run during the base period. Impacts have been substantially reduced since 1985 under the PST, and averaged < 1% of the run in 2002-2004.
Columbia River Summer	The reported catch by this fishery accounted for 8% of the run during 1979-1982, then about 3% of the run from 1985-1998. Impacts observed for 2002-2004 indicate that the reported catch for this fishery represented about 9% of the run, slightly higher than during the base period and 3 times the 1985-1998 impacts.
Columbia River Tule (Cowlitz, Spring Creek, Lower River Hatchery)	The reported catch by this fishery accounted for a small proportion of the run during 1979-1982. Impacts observed for 2002-2004 indicate that the proportion of the run accounted for by this fishery has not changed significantly under the PST.
Lewis River Fall	This fishery has had a light impact on this stock throughout the time series, averaging about 3% of the run from 1981-1998, and then averaging less than 2% since 1999.
Columbia River Bright	The reported catch by this fishery accounted for approximately 6% of the run in 1979-1982. Impacts observed in 2002-2004 averaged about 3% of the run, about one-half the level observed during the base period.
Snake River Fall	Impacts in 2003-2004 averaged about 1% of the run, and were less than one-quarter (25%) of the average impact observed from 1988-1994.
Salmon River Fall (Oregon Coast)	The reported catch by this fishery accounted for about 21% of the run during the base period, then dropped to average of about 12% from 1985-1995, and subsequently dropped again to an average level of about 5% from 2002-2004.

Assignment 8. Provide annual stock compositions through 2004 for the WCVI and NBC fisheries as in Appendix I of TCCHINOOK (04)-4, again with average figures calculated for appropriate prior years compared with average figures for those years for which specific stock concerns influenced the conduct of the NBC and WCVI fisheries;

The PSC Chinook model estimates of stock composition are provided in Tables 8-1 through 8-10. Since the PSC Chinook model does not include representation for all stocks that may be encountered in a fishery, stock composition estimates generated from the model are not directly comparable to those estimated through other means. In addition, the model, as currently constructed, cannot currently account for temporal changes in the conduct of these fisheries. Therefore, model estimates of stock composition provided do not reflect changes in the temporal conduct of the fisheries.

Assignment 9. For the NBC and WCVI fisheries, provide the CTC's assessment of the GSI data that supports the presentations referenced in 2 above and the

stock-specific management plans, and detail how that data may be utilized in advancing our understanding of stock composition in those fisheries;

The Workgroup concluded: 1) small sample sizes result in considerable uncertainty regarding contributions of stocks that comprise a small portion of the catch, 2) GSI sampling in the WCVI fishery was not representative, and 3) there are questions regarding the potential for bias resulting from an unbalanced representation of stocks included in the baseline.

The utility of GSI estimates could be improved by using standardized genetic baselines and standardized procedures for generating and reporting stock compositions. Genetic methods could provide information for fishery management that cannot be readily obtained from CWT experiments. For example, they could detect the presence of major stocks that are not adequately represented by CWTs. Genetic methods are well suited to estimating the catch of major stocks at reasonable cost. However, these methods are not capable of providing estimates of contributions of stocks that comprise small proportions of the catch with a high degree of reliability unless very large sample sizes are taken.

Assignment 10. After the tasks listed above have been completed, outline, in a separate document if necessary, technical difficulties for implementation of the agreed AABM fishery regimes that may be created by fishery patterns that change (possibly in-season) in order to alter the exploitation rates on specific stocks. Include any recommendations for monitoring programs and for analytical methods to estimate stock-specific impacts (across the range of stocks in an AABM fishery) that may result from such alteration in the conduct of a fishery.

The Workgroup noticed that the fishery index (harvest rate index) for the WCVI troll fishery derived from the CWT exploitation rate analyses has consistently deviated from the fishery index estimated by the PSC Chinook Model (Figure 1 below) since 2000. Prior to 2000, the two indices track relatively closely. Since then, however, the values have diverged, with the CWT-based index being consistently higher than the Model index. This suggests that the ability of the Model to accurately reflect impacts of the WCVI troll fishery has deteriorated. The Workgroup developed methods to improve the ability of the Model to estimate the impacts of changing catch patterns for this fishery.

Figure 1. Estimated CWT (through 2004) and PSC Chinook model (through 2005) landed catch fishery indices the WCVI troll fishery, from the 2006 PSC Chinook model calibration.

Two additional analyses were investigated by the Workgroup. The results of these analyses are presented in Section 10 of the report. The first analysis decomposes the annual stock-age specific exploitation rates employed by the PSC Chinook model into monthly stock-age specific exploitation rates. Using this procedure, the stock composition of monthly catches can be estimated. Table 10-1 and Figure 10-1 illustrate how stock composition in the WCVI troll fishery would be expected to change by month. At base period stock abundance levels, Columbia River stocks comprise a larger proportion of the catch earlier in the season (March through June), while Puget Sound stocks comprise a larger proportion of the catch later (September through November). The proportion of Fraser stocks in the catch is predicted to be largest in July and August.

The effect of changes in timing of catch can be represented in the PSC Chinook model by two means: (1) Annual stock-age exploitation rates could be developed by weighting monthly stock-age-fishery exploitation rates by the magnitude of the monthly catch; or (2) annual scalar values could be estimated and used to modify the base period exploitation rates. By combining these adjustments to annual base period exploitation rates with other regulatory measures such as minimum size limits, changes in fishing patterns and regulations could be evaluated. The Workgroup examined the stock composition during three periods with different fishing regimes (1987 to 1995, 1999-2001, and 2002-2004), assuming base period levels of stock abundances.

The methods described above provide a means to modify the PSC Chinook model to reflect the effect of changes in fishery regulations and timing. For fishery planning purposes, the main technical questions relate to the degree to which the fishery timing can be predicted. Unanticipated changes in fishing patterns increase uncertainty in the ability to accomplish stock-specific management objectives. Fishing patterns can change for any number of reasons, either preseason or inseason. Without additional information from managers regarding preseason fishery planning, assumptions regarding fishing patterns must be made. Common assumptions in these cases include the same pattern as observed last year, or a pattern similar to a recent year average. The CTC currently uses these types of assumptions when doing preseason modeling of the SEAK troll fishery. The policy question, simply put, but more difficult to answer is: "How much of a temporal change is too much?" The answer is rooted in policy issues relating to the degree to which deviations from expectations can be tolerated and accommodated by the management system.

The second analysis involved the development of a 'concentration index' to help isolate the effects of fishing pattern changes as reflected in CWT recovery patterns. The concentration index standardizes CWT recoveries by accounting for observed changes in brood year survival, CWT release levels, and fishery catch. By accounting for changes in these factors, any changes in the CWT concentration index can be attributed to one or more of the following confounded factors:

- 1) Changes in the temporal and spatial conduct of a fishery.
- 2) Changes in fishery regulations, such as size limits.
- 3) Changes in stock distribution.
- 4) Changes in stock survival and abundance relative to other stocks.

The results of this analysis are presented in detail in Section 10.

Workgroup Recommendations

The results of this report have led the Workgroup to five specific recommendations. Some of these recommendations will require policy direction from the PSC. Our recommendations are highlighted in bold font; specific requests for PSC guidance are also highlighted in bold font, and bulleted.

Several analyses conducted by the Workgroup suggest that temporal changes in the conduct of the WCVI troll fishery have led to both positive and negative changes in impact on individual stocks of conservation concern. Currently, the PSC Chinook model cannot account for such temporal changes. In this report, a simple means by which such changes could be accounted for in the model is reported. Such changes would be relatively straight forward to implement and would result in a more accurate prediction of both the Abundance Index and model estimates of stock impacts in a fishery. In the Appendix to Annex IV, Chapter 3, assignment 5 instructs the CTC to '...continue to

review and improve the accuracy and precision of the CTC model, including among other things, determining the pre-season forecasts of the aggregate Chinook abundance available to the fisheries.' The proposed model modification would therefore fall under this assignment.

- 1) **The Workgroup recommends that the CTC implement the model changes described in section 10 of this report for the WCVI, NBC, and WA/OR troll fisheries; other fisheries could also be considered.** However, such changes will likely alter the relationship between abundance and allowable harvest as embodied in Table 1 of the Agreement, as well as the predicted AI for all AABM fisheries. The magnitude of the changes is not known at this time. A similar modeling procedure called the Stratified Proportional Fishery Index (SPFI) has been in place for the Alaskan (SEAK) troll fishery for a number of years, which accounts for both spatial and temporal changes in its conduct, and therefore no changes in the model would be required for this fishery. However, the changes to the predicted AI for other fisheries resulting from the proposed model changes, will indirectly change the predicted AIs for SEAK fishery as well, though such changes should be small.
 - Does the PSC wish the CTC to modify the PSC Chinook model inputs to be able to account for variations in the temporal distribution of catch during an accounting year in PST Chinook fisheries? If so, for which fisheries and years?
- 2) **The Workgroup recommends that after the changes described in section 10 are completed, a SPFI type analysis be developed for at least the WCVI, NBC, and WA/OR troll fisheries.** A SPFI approach would enable the PSC Chinook model to account for both temporal and spatial changes in a fishery. This approach would take longer to develop than the methods described in section 10.
 - Does the PSC wish the CTC to modify the PSC Chinook model inputs to be able to account for temporal and, to the extent possible, spatial changes in PST Chinook fisheries? Such a modification would be similar to the SPFI approach currently used for the SEAK AABM fishery (TCCHINOOK 05-3). If so, for which fisheries and years?
- 3) **The Workgroup recommends that preseason management plans for PST fisheries should be as accurate as possible and provided to other jurisdictions in a timely manner, so that they can plan fisheries in their jurisdiction appropriately.** Any changes to such plans should be conveyed to the appropriate parties as soon as possible.

4) The Workgroup recommends improvements in CWT sampling and release tagging strategies as follows:

- Direct sampling of all major sport fisheries for CWTs should be implemented if it results in improved estimates for that fishery.
- All hatchery releases should be associated with a CWT release group. Every release of mass marked Chinook should be associated with a CWT group.
- A review of marking and sampling rates for PST Chinook stocks and fisheries is needed. The Workgroup notes that the PSC CWT Workgroup is currently undertaking this task.

5) The Workgroup recommends that the following points be considered when designing DNA sampling and analysis programs:

- Sampling sizes need to be appropriate for the level of application, and results should be reported accordingly. Precise estimates of individual stock composition for stocks comprising less than 5% of catch requires considerably higher sample sizes than are generally being applied in most fisheries.
- Using CWTs to estimate stock composition of the adipose-clipped portion of catch is not appropriate due to the high number of adipose-clipped hatchery fish currently being released that are not associated with any CWT release group. Consequently, GSI sampling of catch for stock composition purposes should be representative of both clipped and unclipped fish encountered in that fishery.
- The baseline used for GSI analyses of mixed stock fisheries should be the one most representative of the stocks being intercepted. Specifically, in fisheries where Canadian and U.S. stock composition estimates are equally important, it is recommended that the GAPS baseline be used.
- Presentations of GSI analyses should clearly articulate the objectives of the work, any shortcomings/limitations, the sample sizes employed, the baseline used, and report the results at the appropriate level of stock resolution for the sample sizes used.

INTRODUCTION

The October 19, 2005 memo to the Pacific Salmon Commission (PSC) from Jev Shelton and Jerry Kristianson assigns the Chinook Technical Committee (CTC) with ten tasks. The overall objective for these assignments is *"to assemble data that is relevant for determining the factual context surrounding the conduct of Canada's AABM fisheries"*.

In October of 2005, at a previously scheduled session of the full CTC, a workgroup was formed and assignments were made to the individual workgroup members. This report is a product of that workgroup and fulfills the assignments given to the CTC.

What follows is a report comprised of the data compilations and completed analyses, aimed at addressing the assignments. These data compilations and most analyses were presented to the Chinook Interface Group (CIG) in a draft report in February 2006. The draft report, including several additional analyses and recommendations, was again presented to the CIG in July of 2006.

Two appendices are also included. Appendix 1 is an excerpt from the recent expert panel report on the coastwide CWT program wherein the panel discusses potential impacts of inseason management of AABM and ISBM fisheries on stocks of conservation concern. Appendix 2 represents a compilation of information requested from the CDFO genetics lab at the Pacific Biological Station by the CTC regarding methodology used in DNA-based stock composition analyses for the WCVI and NBC troll fishery. This appendix contains much of the information needed by the CTC to assess the validity of the GSI-based method of catch stock composition that formed the basis of several PowerPoint presentations on stock composition of NBC and WCVI Chinook catch.

ASSIGNMENTS

- 1. At the discretion of the co-chairs, assign a workgroup to have primary responsibility for completion of these tasks;***

A workgroup (henceforth referred to as the Workgroup) was formed during a scheduled full CTC meeting in October 2005. Workgroup members include:

U.S. Members

Scott McPherson
John Carlile
John Clark
Dell Simmons
Gary Morishima
Rishi Sharma
Marianne McClure

Canadian Members

Rick McNicol
Gayle Brown
Ivan Winther

- 2. View the presentation of "Chinook and Coho Salmon Genetic Stock Identification" as catalogued on the PSC website (from June 2004), and other related presentations by DFO staff (e.g., Wilf Luedke to the Southern Panel, February 2005; Rick McNicol to the Northwest Power and Conservation Council, July 2005);***

It does not appear that any action is required of the CTC other than review of the presentations and clarification of the basis for the information presented. All of the Workgroup members have seen the presentations referred to. During the course of this review errors were found in the approach used to estimate stock composition for the WCVI troll fishery. The errors were corrected to the extent possible given the available data for the 2004 accounting year, and corrected stock composition estimates for the WCVI fishery are provided in this report. No such problems were found in the approach used in the NBC troll and QCI sport fisheries.

3. Review management plans and supporting information and provide a synopsis of management objectives and actions with respect to specific stock concerns for the NBC and WCVI AABM fisheries from 1995 through 2004. Provide an assessment of the degree to which those objectives were achieved and do so in terms of harvests and of exploitation rates on the stocks of concern;

NBC AABM Fisheries Management

Canadian management objectives for the NBC troll fishery are identified in Table 3-1, along with domestic allocations between gear types. The AABM regime for NBC includes both NBC troll and Queen Charlotte Islands (QCI) sport. The sport fishery receives priority access to Chinook over the troll fishery; therefore all of the management actions to protect WCVI Chinook have been undertaken by the troll fishery. The exception was in 1996 when both fisheries were closed for the summer (Table 3-1). NBC troll fishery openings and management details from 1992 to 2005 are provided in Table 3-2. From 1957 to 1982 fishery openings varied somewhat but typically began April 15th and ended September 30th. Prior to 1957, there were no closed seasons in the troll fishery.

We have included harvest limits and management information from 1982 through 2005 to provide the complete context for the 1995 to 2004 data that were requested. Canada has had concerns for WCVI Chinook stocks since 1995. The NBC troll fishery from 1995 to 2001 was managed to annual total allowable catches and common practice was to reduce total NBC troll allocations to reduce exploitation on WCVI Chinook. From 2002 to 2005 management practices were changed to include specific catch limits for WCVI Chinook, with stock compositions from in-season DNA samples being used to shape NBC troll fisheries (Table 3-1). Canada also had concerns for upper Skeena River and upper Thompson River coho stocks from 1998 to 2000. Time and area closures were used to limit troll impacts on these stocks (Table 3-2).

Troll management harvest limits and actual catches for 2002 to 2005 are presented in Table 3-3. The catch limit of WCVI Chinook was expressed as an exploitation rate of 1.5% in 2002. In 2003, the limit was expressed in pieces (6,811 Chinook) without the related exploitation rate estimate. The 2003 management plan was to catch fewer WCVI Chinook than the 2002 fishery. In 2004 and 2005, the management plan was to achieve exploitation rates that were less than the rate observed in the 2002 troll fishery. The catch limits were also expressed as a NBC troll harvest rate on the return of WCVI Chinook to Canadian waters.

Table 3-1. Landed catch of Chinook salmon by the NBC troll and QCI sport fisheries with Canadian management objectives and PST allocations, 1993 to 2005.

Year	PST ¹ Preseason AABM Ceiling	Total ² PST Catch (1000's)	Canadian Domestic Troll Ceiling	Ceiling Objective	Post Season NBC Troll AABM TAC	Actual NBC Troll Catch (Areas 1-5) ³	QCI Sport Catch
1993	*	257	186,000	263,000 NCBC Chinook catch		161,775	25,297
1994	*	251	160,000	263,000 NCBC Chinook catch		164,493	28,973
1995	*	119	60,000	Conservation of WCVI Chinook.		56,863	22,531

2005	246,600	244	11,600 WCVI Chinook ⁴	<10% ER on WCVI Chinook in Canada <3.3% ER on WCVI Chinook by NBC troll	177,800	172,877	68,800

¹ From 1985-1992, the PST agreed catch ceiling for all north and central coast fisheries combined was 263,000. Increments were added in 1990 and 1991. From 1993-1998, no formal agreement on catch limits was in place. In 1993 and 1994, Canada chose to fish to the pre-1993 ceiling; conservation concerns from 1995-1998 kept Canada's harvest well below this ceiling. Since 1999, catch allowance were developed annually through an abundance based management approach. ER=exploitation rate.

² Up until 1998, catch included all north and central coast landings from Areas 1 to 10. Since 1999, catch reported includes only NBC troll landings in Areas 1 to 5 and QCI sport landings in Areas 1 and 2.

³ Area 1 to 5 troll data from fish slips up to 2000 then from combined hauls & slips thereafter. Troll catch from 1993-1998 is by calendar year and by troll accounting year (Sept-Oct) for 1999-2005, from Table 4-1.

⁴ Ceiling calculated based on forecasted return and expected Alaskan harvest.

Table 3-2. NBC troll directed fishing times, Area 1 to 5 catch and management details 1982 to 2005.

** From preliminary Robertson Creek Hatchery (RCH) 2005 forecast (unpublished data).

¹ Note that CWT exploitation rate (ER) estimates for QCI sport are based on awareness factors from other areas. Consequently, their accuracy is unknown.

² Pre-season limit based on the pre-season forecasted return and the anticipated harvest by Alaska.

³ ER = exploitation rate approximated by NBC troll Catch / (Total Catch in all fisheries + Escapement)

WCVI AABM Fisheries Management

The PST states that catch from the troll and sport fishery off the WCVI be accounted for and managed as an AABM fishery. Active management of the WCVI AABM fishery generally involves the troll fishery only, although sport catch is considered when determining the troll fishery pre-season allocation and any opportunities for a late season fishery to take remaining harvestable surplus. Hook and line harvest by First Nations is assumed to be 5,000 fish, and is included in the AABM troll and sport fishery catch.

The sport catch portion of the WCVI AABM fishery typically ranges from 25,000-40,000 fish annually, with no clear increasing or decreasing trend since 1999. Currently, as part of the pre-season management planning process, managers assume that the outside sport fishery will harvest approximately 50,000 fish, which represents the most recent catch level.

The total allowable catch by WCVI AABM fisheries is based on the abundance index generated from the PSC Chinook model calibration. The commercial catch limits are set with consideration given to the harvest of the recreational fishery and the First Nations fishery. Domestic concerns are then taken into consideration and influence troll openings throughout the year. In September, managers receive outside sport harvest estimates and after taking into account the cumulative troll harvest to that point, fishery managers may allow a September troll opening to harvest the remaining yearly allowable catch.

Management from 1995-1998

For most of this period, WCVI troll fisheries were severely restricted due to concerns for Thompson coho and WCVI Chinook. The total AABM harvest during this period was generally well below allowable limits. In fact, in 1996, there was no troll fishery for Chinook off the WCVI. Interior Fraser coho and WCVI Chinook were both limited to an exploitation rate of <1% in WCVI troll. This resulted in significant disruptions to the WCVI troll fishery through broad area/time closures in 1995-1998. Restrictions were also in place on the sport fishery including area/time closures from 1996-1998 for Chinook and in 1998 on coho. In 1998 the WCVI troll fishery entered into a 3-year pilot study to examine the feasibility of fishing opportunities outside the traditional summer troll season.

Management from 1999-2004

In 1998, policy reform initiatives were undertaken within the Department of Fisheries and Oceans. The 1998 New Directions document (CDFO 1998) describes key aspects of conservation-based salmon fisheries management, including three key components: conservation, sustainable use, and improved decision-making. Within this new policy

framework, the Department emphasized conservation of domestic stocks. Implications to the WCVI troll fishery were significant, and are reflected in the management approaches outlined below.

Since the signing of the 1999 Agreement, the WCVI AABM fishery has been managed under the following general approach. The troll season is divided into fall, winter, summer and spring periods. These fishery components were created by management to provide Area G trollers opportunities to harvest Chinook, while attempting to minimize impacts on certain salmon stocks of concern. The fall and winter fishery allocation is based on the two-year-out forecast from the PSC Chinook model calibration in the spring of that year. Once the official pre-season allowable catch is determined through the model calibration the following spring, allowable troll catch for the remainder of the season is determined by subtracting the expected First Nations plus outside sport catch from the total pre-season allowable AABM catch. The size of the September troll fishery is determined after troll and outside sport catch up to that point is determined: any unrealized AABM catch is allocated to a September troll fishery. Note that fisheries in all periods but winter are shaped around stocks of concern through time and area closures (detailed below). In 1998, the minimum size limit for the WCVI commercial troll fishery was reduced from 67 cm to 48 cm (tip of snout to fork of tail). Since 1999, the minimum size limit has been 55 cm.

From 2000-2004 the WCVI Area G troll fishery has been managed to harvest Chinook in four main seasonal fisheries (spring, summer, fall and winter). Domestically the seasonal Area G troll fisheries have been managed around the following stocks of concern from 2000-2004:

Fishery	Stocks of Concern
Spring troll fishery (April-June)	Fraser Early Chinook Lower Georgia Strait Chinook Thompson River coho
Summer troll fishery (July-August)	Thompson River coho WCVI Chinook
Fall troll fishery (September-October)	Thompson River coho WCVI Chinook
Winter troll fishery (November-March)	Minimal impacts on any of the stocks listed above.

Spring troll fishery

From 1998-2000, fisheries were conducted as controlled assessment fisheries, i.e. catch limits were set well below allowable levels for the purpose of evaluating opportunities to avoid stocks of concern. The first year in which full fleet fishing opportunities were provided was 2001, though catch limits were set well below allowable levels. From 2002 on, the fishery was managed to achieve a harvest closer to the full allowable limits.

In 2000, Area G trollers conducted a small test fishery during the March-May period, and harvested approximately 5,300 Chinook. This fishery was closed in May when coho began recruiting to the fishery, thus minimizing impacts on Thompson coho. In 2001, Area G spring troll fisheries increased their harvest to ~32,000 Chinook; the fishery opening was delayed until April 25, to minimize impacts on Fraser Early Chinook stocks. This fishery was then closed May 28, to minimize impacts on Thompson coho. In 2002, Area G spring troll fisheries increased their harvest to ~119,000 Chinook; the fishery did not open until April 14, to minimize impacts on Fraser Early Chinook stocks. The fishery remained open much longer than usual (closed June 20), as coho encounters (i.e. Thompson coho) did not become frequent until then. In 2003, Area G spring troll fisheries increased their harvest to ~134,000 Chinook; the fishery opening was delayed until April 17, to minimize impacts on Fraser Early Chinook stocks. This fishery then closed June 5 to minimize impacts on Thompson coho. In 2004, CWT analysis from the 2003 spring fishery indicated the Fraser Early, as well as Lower Georgia Strait Chinook (which became a concern in 2004) were most vulnerable in area 123 during April. As a result, the spring troll fisheries were closed in area 123 in April, while they began April 1 in Areas 124-127. This spring fishery operated until May 16, and landed 103,000 Chinook. This left some TAC available for a troll fishery in September, the final amount being determined once the cumulative troll and outside sport catch was known.

Currently the spring troll fishery is managed around concerns for Fraser Early Chinook, Lower Georgia Strait Chinook (2003-present), and Thompson River coho. To protect the Fraser Early Chinook stocks, Area 123 (where this stock is known to be present from CWT and DNA analysis) is closed from mid-March until at least mid-April. The Swiftsure Bank (121), known to be a rearing and nursery area for juvenile salmon, remains closed to reduce impacts on immature fish. Other area and timing closures may be implemented from time to time to minimize impacts on Lower Georgia Strait, and Fraser Early chinook.

Summer troll fishery

The summer troll fishery is currently closed due to the high encounter rates typically experienced by this fishery on Thompson coho and WCVI Chinook.

Fall troll fishery

The fall troll fishery is managed primarily around concerns for Thompson coho and WCVI Chinook. To reduce the impacts of this troll fishery on these two stocks of concern, Area G fisheries management implements two restrictions. First, the troll opening is delayed until mid-September, when Thompson coho are assumed to no longer be prevalent in the mixed stock area. Second, all the nearshore areas one nautical mile from the surfline in Areas 123-127 are closed to protect returning WCVI Chinook. In recent years Area 123 remained closed throughout September and Areas 124-127 opened 2-5 miles seaward of the surfline in an effort to continue to protect any migrating WCVI Chinook stocks from exploitation. CWT and otolith information indicates

that the nearshore areas along the WCVI are the areas where most WCVI Chinook are intercepted; therefore these areas remain closed when these two stocks are most vulnerable to exploitation from the troll fishery.

Winter troll fishery

Due to the low harvest during the November-March period, it is assumed that impacts are minimal on WCVI and Lower Georgia Strait Chinook stocks.

Managing Around Domestic Stocks of Concern

Coho

From 2000-2004 the most prominent stock of concern that managers have had to address in the Area G (Areas 21-27, 121 and 123-127) troll fisheries is the Thompson River coho stock. During this time period Thompson River coho were managed to a total Canadian coastwide exploitation of 3%, and over the last four years the exploitation rate from the WCVI Area G troll fishery has been 0.3% or less. Exploitation rate estimates are calculated pre-season using CWT information and modelling techniques, and evaluated post-season. Post-season estimates differed very little (<0.1%) from pre-season estimates (Table 3-4).

Table 3-4. Estimates of pre-season expected exploitation (ER) rates, and post-season ER rates for Thompson River coho, 2000-2004.

Year	Total Expected CDN ER Rate Estimates on Thompson Coho	Pre-season Expected WCVI Troll ER Rates on Thompson Coho	Post-season Estimates of WCVI Troll ER Rates on Thompson Coho
2000	NA	NA	NA
2001	0.9%	NA	0.17%
2002	2.0%	0.21%	0.29%
2003	1.1%	0.07%	0.07%
2004	2.5%	0.14%	0.07%

Chinook

From 2000-2004, fishery managers have also structured the Area G troll fishery to accommodate domestic concerns for WCVI Chinook. During the 2000-2004 period, WCVI Chinook have been managed to a total Canadian coastwide exploitation rate of 15%, and over the last four years the exploitation rate limit for the WCVI Area G troll fishery has been 0.3% or less. Pre-season expected impacts are estimated via CWT analysis and post-season exploitation rates are determined through CWT analysis.

Table 3-5. Estimated exploitation rates for WCVI Chinook stocks based on RBT in WCVI AABM fisheries, 2000-2004.

Preseason Allocation/Expected Impact				Postseason Exploitation - CWT/cohort analysis	
Year	WCVI Troll	WCVI Sport	Total Canadian ER	WCVI Troll	WCVI Sport
2000 ¹			5.0%	0.0%	0.0%
2001	0.4%	2.5%	5.0%	0.0%	1.9%
2002	0.5%	4.5%	10.0%	0.4%	2.0%
2003	0.4%	6.0%	15.0%	0.0%	4.4%
2004	0.5%	6.0%	15.0%	0.1%	1.2%

¹ No specific exploitation limits were set that year.

Two other Chinook stocks of concern that are managed within the WCVI Area G troll fishery are Fraser Early Chinook and Lower Georgia Strait Chinook. Neither stock is managed to a harvest rate or an exploitation rate limit. Rather, CWT and DNA analysis are conducted post-season to provide fisheries managers with information on where and when the largest fishery impacts occur. This information is used in the pre-season planning of the Area G troll fishery, and the openings are structured to avoid the areas with the largest potential impacts on these two stocks of concern. For reference, pre-season allowable catch, pre-season sector allocation, as well as post-season catch are provided from 1999-2004 (Table 3-6).

Table 3-6. The 1999-2004 AABM Chinook allocation and achieved harvest by WCVI AABM fisheries. Catch is from Section 4.

¹ First Nations catch is not monitored, and is assumed to amount to 5,000 fish annually.

² Troll catch reported includes First Nations catch and is the total AABM troll catch by accounting year.

4. For the years 1979-1998, and 1999-2004 provide effort and catch data by month (or other appropriate time period) by management area (or sub-area as appropriate) for the NBC and WCVI AABM fisheries;

Landed Catch

Landed catch is provided for both WCVI and NC AABM fisheries, by sector, for the years 1979-2004. Monthly breakouts are further provided for the troll fisheries. However, monthly breakouts are not provided for the sport fisheries. Such breakouts were not deemed to be informative, as both the WCVI outside sport fishery, and QCI sport fishery are summer-only fisheries (June-August), with catch and effort occurring in a fairly consistent manner across the summer months from year to year. However, the WCVI sport catch was broken out by catch region, i.e. Southwest Vancouver Island (SWVI; Areas 21-24) versus Northwest Vancouver Island (NWI; Areas 25-27). Since CWT recoveries are expanded based on catch sampling within a catch region, such a breakout would capture any large geographic shift in sport catch within the WCVI sport sector across years.

Troll

Both the NBC and WCVI troll fisheries have exhibited similar changes over time. During the base period (1979-1982), NBC troll catch occurred in all months from April to October, with the majority of catch occurring in the summer months (Table 4-1). Starting in the late 1980's, catch occurred primarily in the summer months, including September, with much smaller amounts landed in the spring. However, by the early 2000's, fishing once again occurred in the spring months, in addition to the summer, though the August fishery was essentially shut down due to conservation concerns for WCVI Chinook. Similarly, WCVI troll catch during the base period occurred from spring through early fall, with the majority of catch occurring in the summer months (Table 4-4). By the late 1980's, the WCVI troll fishery catch occurred almost exclusively during the summer months. By the late 1990's, most catch was landed in the spring and fall. However, unlike the NBC fishery, very little catch now occurs in the summer. Note that during the base period, ~81% of total catch occurred in SWVI. However, in subsequent years, the proportion of catch from this catch region declined significantly, though still accounting for the majority of WCVI troll catch (Table 4-2, 4-3).

Table 4-1. NBC troll Chinook catch by month and year, 1979-2004 (from RMIS database¹). Note that the PSC accounting year is from October to the following September.

¹ Some data inconsistencies were noted between RMIS catch and catch data compiled by area DFO staff from 2001-2004, that could not be resolved prior to the compilation of this report. Consequently, area staff data were used for these years. Note that Dec catch reported in RMIS actually represents the sum of catch from Jan, Feb and Dec of that calendar year. Also, for CWT expansion purposes, some catch may have been considered landed in a different month than reported (e.g. freezer troll catch). Consequently, the PSC accounting year totals based on the above data may not equal those actually used for PSC Treaty accounting purposes. They are provided here to illustrate the degree to which annual and catch accounting year totals can differ.

¹ Note that Dec catch reported in RMIS actually represents the sum of catch from Jan, Feb and Dec of that calendar year. Also, for CWT expansion purposes, some catch may have been considered landed in a different month than reported (e.g. freezer troll catch). Consequently, the PSC accounting year totals based on these RMIS data may not equal those actually used for PSC Treaty accounting purposes. They are provided here to illustrate the degree to which annual and catch accounting year totals can differ.

Sport

The QCI sport fishery essentially did not exist during the base period. It wasn't until the late 1980's that this fishery began to expand significantly, as lodges were built in this area. The proportion of AABM catch harvested by this sector has been growing significantly over the past three years (Table 4-5).

Table 4-5. QCI sport Chinook catch, 1985-2005.

Year	QCI Sport (stat areas 1, 2)
1985	600
1986	1,153
1987	2,644

2002	47,100
2003	54,300
2004	74,000
2005	68,800

While fishing in time and areas associated with the WCVI outside sport fishery has been occurring since the base period, it hasn't been until 1992 that efforts were made to keep separate catch records of inside versus outside sport catch. This fishery tends to be limited in capacity, with no strong trend in catch over the past 13 years (Table 4-6). More recently, the fishery typically lands between 25,000 and 40,000 Chinook. The large majority of catch by this sector occurs in the SWVI. There has not been any trend in redistribution of catch between these two catch regions since 1995 (Table 4-6).

Table 4-6. Annual WCVI outside sport catch of Chinook salmon by catch region, 1995-2005.

Year	SWVI	NWVI	Total Outside Sport
1995	13,485	471	13,956

2005	52,900	2,893	55,793

Troll Effort Data

While effort information for both Canadian AABM troll fisheries is reported routinely, such effort data is not species specific, since troll openings may allow harvest of multiple species. Consequently, inferences regarding changes in effort directed at Chinook, specifically, cannot generally be derived from these data. While such multi-species troll openings have been much less common in recent years, historically they were common. In addition, use of these data for making inferences regarding spatial changes in effort is also not advised. Frequently, a total amount of effort (e.g. number of boat days) is reported across several statistical areas. Since effort is reported by gear and statistical area, a 'guess' is made by sampling personnel as to how much of the effort is spent in one statistical area versus the others. In such instances, effort may be assumed to be equal for all statistical areas, which may or may not be an accurate representation on where effort was actually expended. In addition, catch reported in the RMIS database has been adjusted to account for when freezer troll catch was assumed to have been caught, as opposed to when it was landed. Effort in the CDFO sales slip database, where effort information is housed, has not been adjusted in a similar manner. Consequently, effort and catch data in the tables presented here will not be properly matched. Because of the above, troll effort data is presented here merely for illustration, and should not be used for any analytical purposes without prior consultation with CDFO personnel.

Table 4-7. Effort in the Northern troll fishery for all salmon species in boat-days by month and year, 1979-2004. Data are from the CDFO sales slip database. Note that totals for December actually represent the sum of effort for January, February and December of that calendar year.

5. To the extent possible, compare stock composition data available from coded wire tag recoveries and from the CTC Chinook model for the years 2000-2004 to the GSI data assembled by Canada to facilitate recent management of the NBC and WCVI fisheries.

After some discussion, the Workgroup concluded that this assignment amounted to an exercise of comparing 'apples to oranges'. Therefore, no such comparison has been made. Rather, GSI-based stock composition estimates are provided for some fisheries and years, where available. Model estimates of stock composition are provided under assignment 8.

CWT data alone cannot be used to estimate the stock composition in a fishery of interest because only a portion of the catch (typically 30-50%) can be assigned to a stock group. All hatchery and wild stocks present that have no CWT data associated with them will not be detected. Only GSI-derived (which may incorporate CWT information) and model stock composition estimates attempt to assign the entire catch to stock groups. However, these two approaches are designed with different objectives: GSI will theoretically detect all stocks present, while the PSC Chinook model will only estimate stocks included in the model base period. For example, while GSI can estimate the number of California Chinook in any catch (assuming that adequate baseline information on component stocks is available), the Chinook model cannot, since California CWT recovery information from the base period was not incorporated into the model. For the WCVI fishery, GSI-based stock compositions were estimated only for fish with intact adipose fins. Therefore, these estimates would not report the total contributions of hatchery and wild fish. Consequently GSI and PSC Chinook model-based estimates are not comparable. While comparing a GSI-based stock composition estimate to a model estimate may have some utility, such comparisons are only valid for the North Coast troll and QCI sport fisheries. These fisheries were the only ones sampled in an unbiased and representative manner using DNA technology for the period covered by this report.

NBC AABM Fishery Catch Stock Composition

The NBC information provided consists of GSI data from the NBC troll fishery and the Queen Charlotte Islands (QCI) Sport fishery (Winther et. al. 2006). The CTC Chinook model generates stock composition data for the annual time step from October 1 through September 30 of the following calendar year. The GSI information from the NBC AABM fisheries has been assembled to provide annual stock specific catch estimates for the troll and QCI sport fisheries in the same time steps (e.g., the 2003 CTC year begins Oct. 1, 2002 and ends Sept. 30, 2003). Stock compositions are presented in number of fish for the NBC troll fishery from 2002 to 2005 in Table 5-1A and for the QCI sport fishery from 2003 to 2005 in Table 5-2A. The stock composition estimates for catch by these fisheries are presented as percentages in Tables 5-1B and 5-2B for troll and sport fisheries respectively. The baseline used for sample allocations

as well as a key to the acronyms used to represent production regions are provided in Tables 5-3 and 5-4.

Virtually all of the troll catches from 2002 to 2004 were assigned to stock groups using GSI information. However, small amounts of catch in each of the years could not. For example, test catches from Hecate Strait were not analyzed in 2002 and small catches in October of 2002 and 2003 were not sampled. Similarly, small portions of the annual QCI sport catches were not included in the GSI analysis (i.e., small catches from the east side of QCI). These small amounts of catch would have minimal effect on the stock composition estimates over the entire annual catch.

DNA samples were collected from 10,800 of the 13,100 Chinook caught in the 2001 troll fishery. The Area 4 catch of 2,300 Chinook was not DNA sampled. Only 381 Chinook in the 2000 catch of 9,948 were sampled for DNA analysis. Because this fishery was so restricted those years (less than 10% of the preseason NBC AABM allowance was harvested), comparisons to model estimates of stock composition would not likely be valid for 2000 or 2001.

Table 5-1A. Estimated Chinook catch by stock group for NBC troll fisheries from 2002 to 2005, based on DNA analysis. Baseline stocks appear in Table 5-3; abbreviations are described in Table 5-4, and standard deviations (STD) appear in brackets.

WCVI AABM Fishery Catch Stock Composition

In the WCVI troll fishery, CDFO attempted to use data collected from CWT and DNA sampling to generate stock composition estimates for marked (adipose-clipped fish) and unmarked fish separately. These estimates were combined in various past PowerPoint presentations (e.g. Northwest Power and Conservation Council meeting, July 2005). Specifically, DNA samples were taken from unclipped fish only, while CWT recoveries were expanded to account for associated production with CWT releases, in an attempt to account for the stock composition of adipose-clipped fish. However, upon closer examination of the 2003/2004 WCVI troll stock composition data, the Workgroup determined that the approach used was flawed. There were four major sources of error:

- 1) During the course of transferring release data from the RMIS database to the Canadian equivalent (Mark Recovery Program Database), a 'translation' error occurred. This resulted in some release data having their mark status incorrectly identified. The net effect of this error was that expansions of some CWT recoveries for southern U.S. stocks were incorrectly calculated.
- 2) Some incorrect weights were applied to the monthly stock composition estimates.
- 3) When attempting to account for all hatchery releases, it was incorrectly assumed that all adipose-clipped fish encountered in the WCVI troll fishery had CWTs associated with them. In fact, from 30-45% of recent adipose-clipped Chinook releases from the southern U.S. are not associated with any CWTs. This is primarily the result of mass marking. Based on the observed clip rate in the 2003/2004 WCVI troll catch versus the calculated number of clipped fish encountered in the catch that could be accounted for by CWTs, it is estimated that approximately 50% of clipped encounters were from unassociated releases. This meant that ~12% (monthly range, 4-25%) of the total WCVI troll catch for that period was not accounted for, i.e. was not represented by either CWTs, or DNA sampling. Efforts to try to link unassociated releases with CWT marked releases generally failed, as such releases could not be reliably associated with CWT marked fish of similar stock origin, life history type, or run-timing. The only conclusion that could be drawn on the origin of this unassociated, clipped catch is that it is almost exclusively comprised of southern U.S. hatchery origin Chinook.
- 4) Another source of confusion resulted from inconsistencies in the stocks included in the groupings used for CWT and DNA analysis. In particular, the stock group labelled mid-Columbia Springs actually represented lower Columbia spring stocks originating below John Day Dam, or in the Yakima basin. This inconsistency has now been eliminated and stock groups properly labelled.

The net result was that even when errors #1 and 2 were corrected, there was no reliable way to account for 12% of the landed catch for the 2003/2004 accounting year (error #3). Therefore, the stock composition estimates previously presented as representing the total WCVI troll catch for this catch year were incorrect. Nevertheless, since the 2003/2004 WCVI troll stock composition estimates have been widely circulated, the Workgroup felt that corrected results, as far as they could go, should be provided in this report. No additional stock composition estimates are provided for the WCVI troll

fishery, since it has only been since the fall of 2005 that the sampling protocol was changed so that both clipped and unclipped fish are sampled for DNA. Such sampling should provide unbiased, representative estimates of stock composition in the future (see Appendix 2 for a complete description of the GSI methodology employed by CDFO, including the stocks included in the CDFO microsatellite baseline).

A graphical comparison is provided between the stock composition estimates for the WCVI troll (2003/2004) presented at the Columbia River Power and Conservation Council (Figure 5-1), and the corrected and revised estimates (Figure 5-2). A tabular comparison is shown below. Monthly estimates of stock composition are also provided in Table 5-5 (see Assignment 9 for an assessment of the methodology used).

Stock Group	Previously Presented (July 2005) Stock Composition	Corrected Stock Composition
Alaska	0.0%	0.0%
Canada	12.1%	13.2%
Puget Sound Spring/Summer/Fall	19.4%	17.7%
Washington Coastal	1.3%	1.2%
Lower Columbia R Fall	43.5%	27.8%
Upper Columbia R Spring	0.1%	0.0%
Upper Columbia R Summer/Fall	4.3%	9.3%
Lower Columbia R Spring	5.3%	7.0%
Upper Willamette Spring	4.0%	4.6%
Snake R Spring/Summer	0.1%	0.2%
Snake R Fall	1.5%	1.6%
Oregon Coastal	1.6%	1.9%
California	5.9%	3.7%
Unassociated adipose fin clipped	NA	11.9%

Some changes associated with correcting errors 1-4 are worth noting. The proportion of Lower Columbia River fall Chinook was originally overestimated, while that of the Upper Columbia River spring/summer group was underestimated. Changes among the other stock groups were relatively small. Note that when the unaccounted for adipose-clipped portion is included in the breakouts, the proportions of all of the identified stock groups decrease, though some of these stock groups would also be represented within the unassociated group to an unknown degree. Table 5-6 provides a tabular presentation of the percent stock compositions for both figures.

It is important to note that these point estimates have measures of variability associated with them. Consequently, caution should be exercised when using any such point estimates to estimate how many fish of any stock group were harvested.

Figure 5-1. Estimated stock composition of the WCVI Chinook troll catch (Oct. 2003 – Sept. 2004) based on combined DNA and CWT data as presented at the Northwest Power and Conservation Council meeting, July 2005. CWT and DNA used to construct this chart were assumed to represent 100% of the catch. However, a number of errors were later discovered in the assemblage of the CWT data. In addition, it was discovered that the stock composition data actually represented only 88% of the catch. Note that Alaska stocks are represented at the 12:00 position; the other stock groups follow in the order given in the legend in a clockwise direction. The acronym 'AFC' refers to 'adipose fin clip'.

Figure 5-2. Estimated stock composition of the WCVI Chinook troll catch (Oct. 2003 – Sept. 2004) based on combined DNA and corrected CWT data. This is similar to Figure 5-1 except that the estimated percentage of the catch not represented by either CWT or DNA sampling has been included, labelled "Unassociated AFC". The stock-specific percentages have been adjusted (i.e., reduced) so that their total plus the unrepresented AFC (adipose fin clip) component now represents 100% of the catch.

Table 5-5. Monthly estimated stock composition estimates (both uncorrected and corrected) of the WCVI troll catch based on combined CWT and DNA data during the period Oct. 2003 – Sept. 2004. Figure 5-1 represents the data in the column with the heading 'Mean – Original Uncorrected'. Figure 5-2 represents the data in the column with the heading 'Mean – Corrected'. See the text for an explanation of how the original data were corrected.

AFC fish NOT associated with a CWT release group	No ¹	22.0%	21.8%	18.5%	16.9%	24.5%	17.8%	14.7%	4.4%	10.4%	16.8%	11.9%
Landed Catch (Monthly and Total)		17,905	2,803	815	1,390	1,812	8,043	51,181	51,486	31,234		166,669

¹ While the stock composition of this component could only be accounted for via DNA, no tissue samples were taken from this component of the catch.

6. Specify the sampling levels and procedures employed in each fishery and time period for CWT and GSI data for the years 1985-2004;

Mark Recovery Program (CWT sampling)

Troll Fisheries

CDFO has required that all commercial troll catch be sampled at a minimum rate of 20% of landed catch. Sampling is to represent the distribution of catch across statistical areas within a catch region, such that any CWT recoveries can be expanded by each statistical week in which catch occurred for each catch region. Such sampling is meant to provide unbiased and accurate expansion factors for all CWT recoveries. For north coast troll, the catch region NTR is comprised of statistical areas 1-5, corresponding to the statistical areas encompassed by the North Coast AABM troll fishery. While every effort is made to ensure that catch sampling is representative of catch in all statistical areas, CWT expansion factors are based on catch sample rates across all statistical areas comprising the NTR catch region.

For the WCVI area, there are two catch regions: SWVI, encompassing statistical areas 21, 23, 24, 121 and 123-124; and the NWVI, encompassing statistical areas 25-27 and 125-127. Together, these two catch regions comprise the statistical areas that correspond to the WCVI AABM troll fishery. As with the NBC troll fishery, efforts are made to representatively sample catch in all statistical areas within each catch region. However, WCVI CWT expansions are based on catch sample rates for NWVI and SWVI separately. For both NBC troll and WCVI troll fisheries, expansion factors do not take into account the particular statistical area location where the fleet fished.

Up until 2003, all commercial catch sampling was carried out by J.O. Thomas and Associates (JOT), a Vancouver-based consultant. Starting in 2003, catch in southern B.C. fisheries was for the most part, sampled by CDFO staff using the same operational guidelines as those used by JOT, while north coast catch continued to be sampled by JOT.

For NBC troll, representative sampling is complicated by landings from the freezer fleet, which can comprise up to ~60% of troll catch some years. Since freezer boats might fish for weeks before landing, their catch often occurs across statistical weeks and catch region boundaries, making it difficult to determine the proper catch sample expansions. Furthermore, prior to 2004, many CWTs dissected from heads collected from the freezer fleet could not be considered random, due to concerns regarding bias. Consequently, more effort was directed at sampling the ice boat fleet during this time. However, tag expansions were based on both ice boat and freezer troll landings, under the assumption that both fleets were fishing in similar areas and times. Recent analyses by CDFO personnel have demonstrated that the stock composition of catch for these two troll fleets is similar. Since 2004, catch sampling of the freezer fleets has been much more representative.

For most years, the 20% catch sample rate was achieved on an annual scale (Fig. 6-1 and 6-2), though monthly rates could vary considerably (Tables 6-1 and 6-2). Only in 2003 for the NBC troll fishery, was the annual sample rate significantly below 20% (Fig. 6-2). The achieved rate of 13% was due primarily to a problem with expanding CWT recoveries in the freezer troll fleet due to incomplete catch information that led to questions of possible bias in CWT collection. As a result, CWT recoveries for much of this catch had to be considered as 'select'. Consequently, while ~26% of the landed catch was sampled for CWTs, only half of the sampled catch (i.e. 13% of all landed catch) could be used for CWT expansions.

Figure 6-1. Annual Catch Sample Rate for WCVI Troll, 1985-2004

Figure 6-2. Annual catch sample rate for Northern BC troll, 1985-2004.

Table 6-1. Monthly and yearly Chinook catch sample rate and landed catch for WCVI troll fishery, in total, and by the NWWI and SWWI catch regions, 1985-2004. Note that while the small amount of catch caught from vessels that crossed the NWWI and SWWI border is included in landed catch totals, none of the CWTs sampled from such catch can be used. That is because tag expansions are done separately by these two catch regions, and there is no reliable way to apportion tags recovered from such catch by catch region. Catch sample data from RMIS database.

PANEL A—All areas of the WCVI troll fishery

Year		Month										Annual Catch Sample Rate
		Mar	Apr	May	Jun	July	Aug	Sept	Oct	Nov	Dec

Sport Fisheries

The QCI sport fishery portion of the NBC AABM fishery is located off the Queen Charlotte Islands in statistical areas 1 and 2. The WCVI outside sport fishery is included in the WCVI AABM fishery, occurring in parts of statistical areas 21, 23-27, 121 and 123-127. However, the exact portion of these statistical areas that comprise this fishery is seasonally dependent (see the 1999 Agreement for the exact definition).

Since 2002, there has been little direct sampling for CWTs in any Canadian sport fishery. The CDFO has relied on a voluntary head recovery program to obtain CWT samples from its sport fisheries, whereby sport fishers are encouraged to deposit the heads from adipose-clipped Chinook in specially designated depots. Based on adipose-clip rates observed during creel surveys, an 'awareness factor' is calculated that represents the fraction of the estimated number of adipose-clipped Chinook encountered in a sport fishery from which heads were voluntarily submitted for CWT extraction. The inverse of this factor is used to expand each CWT caught in the particular area and time stratum that the expansion factor represents. These awareness factors are analogous to catch sample rates in the commercial fishery. Because creel surveys are not conducted for each sport fishery, awareness factors for any one fishery and time stratum may be based on the calculated factor from the nearest geographical location. In some cases where creel estimates are not available, a default awareness factor of 0.25 was used, leading to an expansion factor of 4 (i.e. $1/0.25$) for that particular time and area stratum.

While a creel survey has been conducted on the QCI sport fishery since 1997, the awareness factors currently used to expand CWT recoveries in this fishery are based on data from other areas, and are not derived from the QCI sport fishery. Consequently, while CWT recoveries from this area are representative of the stocks encountered in this fishery, the awareness factors used to expand these recoveries are not based on data from this fishery. However, QCI-specific awareness factors (and the corresponding corrected expansions for CWT recoveries since then) will soon be incorporated into the RMIS database. Comprehensive creel surveys have been conducted off the WCVI since 1996. Awareness factors used to expand CWT recoveries in WCVI sport fisheries are based on all heads submitted from WCVI sport fisheries, i.e., both the inside and outside sport fishery combined.

From 1985-2004, average awareness factors for the WCVI sport fishery ranged from 3.6-26.6%, while those for QCI sport ranged from 7.5-32.0% (Table 6-3 and 6-4).

Table 6-3. Awareness factors used to expand CWT recoveries in the QCI Chinook sport fishery. Expansion factor used to calculate awareness factors from RMIS database.

GSI Catch Sampling

Since at least 1998, microsatellite DNA has been used for Chinook stock identification in B. C. fisheries. Originally, such sampling was meant to establish presence or absence of certain stocks of concern. It wasn't until 2002 that attempts were made to use this technology to estimate stock composition of a full season's catch in any Canadian AABM fishery. Most such work was directed at troll fisheries, since they account for the majority of catch in Canadian AABM fisheries and would be the first fishery required to make a management adjustment under the current allocation policy. However, some DNA sampling has recently been conducted on both the QCI and WCVI outside sport fisheries. Sampling approaches, protocols, etc. are described below for each fishery and sector.

NBC AABM Fisheries

GSI samples were first collected from the NBC troll fishery in 2000 and from the QCI sport fishery in 2002 (Winther, 2005 and Winther et. al., 2006). First collections were preliminary or exploratory in nature with the objectives of testing GSI and sample collection techniques.

A common paper punch was used to collect tissue samples from the operculum of the Chinook salmon sampled. One tissue sample was collected from each Chinook. Tissues were preserved in a solution of 95% non-denatured ethanol. Chinook salmon collections were compared against genetic baselines from Chinook salmon populations from SEAK through Canada and the northwest U.S. A baseline of 182 populations was used early in 2002 then revised to 233 populations in 2003, and to 240 populations in 2004 (Table 5-3). Samples were analyzed for 13 microsatellite loci using methods of DNA extraction, PCR reaction, electrophoresis, and allele scoring described by Candy et al. (2002) and Nelson et al. (2000).

The Molecular Genetics Laboratory provided the sample analysis. A new version of the computer program as outlined by Pella and Masuda (2001) was developed and used for the analyses presented here. This program called "c-BAYES" is available upon request from the Fisheries & Oceans Canada, Molecular Genetics Laboratory at the Pacific Biological Station in Nanaimo. The model output presented includes the Bayesian probability estimates for the five most probable populations for each sample (J. R. Candy, Fisheries & Oceans Canada, pers. comm.).

1) NBC Troll

Some GSI samples were collected from the NBC troll fishery in 2000 (Table 6-5), though only a small sample was analysed (n=88). A more extensive program was undertaken in 2001 with almost 20% of the Area 1 and 2W troll fisheries sampled for DNA (2,057 individuals sampled). NBC troll fisheries in 2001 were held with a limited number of participants and sampling of Chinook landings was mandatory. Collections were made as "batch" samples where tissues were only matched to the area fished and the week of landing. Samples from multiple vessels were pooled in the same vial for

the same week and area fished. Tissue samples were collected in conjunction with the existing CWT Mark Recovery Program (MRP) contract. The MRP contract objectives are random samples of 20% of vessel offloads by landing week and Pacific Fishery Management Area, Area G in this case.

Samples collected from the 2002 commercial fishery and the 2004 spring fishery were also stored with multiple fish samples per vial ("batch" samples). All other tissue samples were kept in individual vials. Data on the geographic location, date, sampler and other biological data were collected with each sample. Samples were forwarded to the Fisheries & Oceans Canada, Molecular Genetics Laboratory at the Pacific Biological Station in Nanaimo.

A test fishery was conducted in 2002 to collect biological data from major Chinook troll fishing locations in the North and Central Coast. The design was to sample 10 locations during four periods of 15 days each in July and August of 2002. Catch and sampling targets were set at 100 legal sized Chinook and up to 100 sublegal Chinook encountered while fishing for legal Chinook. Only 2,211 of the 4,000 legal sized Chinook proposed for the test samples were taken. Analyses were completed for 788 of the Chinook from the West Coast of QCI. Hecate Strait and Dixon Entrance samples were not submitted for analyses.

The 2003 GSI sampling protocol was to sample test-vessel catch in a manner that would represent 1% of the NBC troll catch. In 2003, all Chinook GSI samples were collected by test vessels at sea. Monthly samples were collected from two locations during closed times. The 2,600 Chinook tissues collected were sub-sampled to 1,775 to best represent the troll catch by time and area.

The sampling objective for the 2004 commercial fishery was to analyze 1,000 Chinook samples representative of the catch. Collections of 1,580 Chinook from the commercial fishery were sub-sampled and 1,143 were analyzed. The test fishery sample objectives were met with 800 Chinook sampled and GSI analyses completed for 768.

Catch was sampled from the 2005 Individual Transferable Quota (ITQ) demonstration fishery and the regular derby style fishery. The objective was to collect tissue samples from 1.5% of the catch (2,400 Chinook) and have the DNA analyses completed for approximately 1% of the catch (1,600 Chinook). Fishery sampling objectives were met with a total of 2,648 Chinook sampled, 2,198 and 450 Chinook sampled from the ITQ and derby fisheries respectively. Analyses were completed for 1,069 of the tissues collected from fishery landings. Requests for analyses were reduced as many of the test samples occurred in the same time and area as the fishery samples.

The 2005 test fishing program was designed to collect 16 samples over 8 time periods and 2 locations between May 1 and September 15, 2005. The tests began in early May to sample 100 Chinook from each of 2 sites: Area 101 between Langara and Frederick Island and Area 2/142 around Buck Point. Samples were collected near the beginning and middle of each month such that stock composition data could be supplied to the managers and reported near the 1st and 15th of each month. No test vessel sampling occurred during the period from June 15 to July 1 because managers expected

commercial opportunity to provide fish for direct sampling of the fishery. Complete samples were collected by the test fisheries except in September. Only 56 and 33 Chinook were collected in the September sample in areas 1/101 and 2W/142, respectively, due to bad weather. The total test catch was 1,489 Chinook and DNA analyses were completed for 1,427 of the Chinook landed by test fisheries.

Commercial fishery samples from 2002 to 2004 were collected from the first fish encountered by the samplers. In 2005, the procedure to sample commercial fishery landings was modified to sample every 5th or 10th fish from a load depending on the size of the load. Typically, 25 or 50 Chinook were sampled from a randomly selected vessel offload. Test fishing vessels sampled the first fish encountered in all years. Note that only samples from legal-sized fish were used for catch stock composition estimates.

2) QCI Sport

The first collections of Chinook tissue for DNA analysis in QCI were sponsored by the Sport Fishing Institute of British Columbia in 2002 (Table 6-6). The proposed sampling strategy was to sample two fish per day from 10 lodges. These voluntary samples were largely a failure as few lodges participated and only samples from a single lodge, representing only part of the fishing season, were suitable for analysis.

Subsequent samples were coordinated by CDFO and collected by Haida Creel Survey staff and volunteer lodges. A voluntary sample was collected from Area 2W in 2003 that consisted of Chinook tissues collected at random from lodge catches at Kano Inlet. In all other collections, the protocol was stratified to sample to five Chinook per day with a maximum of 25 per week from the end of May to early September, essentially covering the duration of the fishery. Collections were made from lodge catches at Langara Island to represent Area 1 & 101 and from Englefield Bay to represent Area 2W & 142. Similar collections were made in 2003 and 2004 from Naden Harbour, but were not submitted due to budget constraints in 2003 and sampling bias in 2004. In 2003 and 2004, the Langara Island collections were sub-sampled to meet budget requirements. Tissue collections from Chinook salmon from the QCI sport fishery for the purposes of GSI are detailed in Table 6-6.

Table 6-5. GSI samples collected from Chinook catches in the NBC troll fishery, 2000 to 2005.

n = number of samples collected

GSI = analysis completed for this number of samples.

Batch = Samples from multiple vessel landings were pooled in the same vial for the same week and area fished.

Test = Samples collected at sea by test fishing vessels in individual vials with associated biological data.

Troll = Samples collected from NBC troll fishery landings in individual vials with associated biological data. A maximum of 50 fish were sampled per vessel. Consecutive samples were collected starting from the first fish encountered, except in 2005, when every 5th or 10th fish was sampled, depending on load size.

IVQ = individual vessel quota

Table 6-6. GSI samples collected from the QCI sport fishery catches of Chinook salmon, 2002 to 2005. n = number of samples collected; numbers in 'GSI' column represent the number of samples analysed.

WCVI AABM

1) WCVI Troll

GSI sampling of this fishery started in 1998, and was initiated in an attempt to determine the presence/absence of WCVI Chinook by time and area strata. This information was used to determine when and where the troll fishery was encountering WCVI Chinook. At this time, there was no intent to estimate stock composition of the full troll catch. As there is a large body of stock composition-related information from CWT recoveries for months when troll fisheries traditionally have taken place, DNA sampling initially tended to occur in months for which little CWT-derived stock composition data existed, i.e., October-April.

It wasn't until the 2003/2004 troll season (October 2003-September 2004) that attempts were made to provide an unbiased estimate of stock composition of troll catch across the full season. The approach used CWT recoveries to represent the adipose-clipped portion of catch, and DNA to estimate the stock composition of the unclipped portion of the catch. Consequently, DNA sampling, in most instances, was done on unclipped fish only. Unfortunately, this approach did not account for the clipped portion of catch that was not accounted for by CWTs (i.e., mass-marked fish not associated with a CWT release group). Thus, in 2003/2004, this meant that stock composition estimates could be estimated for only ~88% of the landed catch (Table 5-6). More details on this and other sampling issues associated with this fishery are provided in the response to question 5. Table 6-7 provides details on when and where tissue samples were collected in this fishery from 1998-2004.

Table 6-7. Details on GSI sampling of the WCVI troll fishery from 1998-2004.

Notes

1. DNA samples chosen for processing, out of all samples collected, were selected based on a weighting by total observed landed catch in each sampled troll zone for that month.
2. Only unclipped fish sampled, in a quasi-representative manner, i.e. a sampler might be told to collect 10-20 plugs per boat. However, depending on the situation, sampling may be done at the boat (unsorted catch) or at the processing plant (sorted catch). DITs were screened out using wands, and thus not included in DNA samples.
3. Same as 2., but no electronic pre-screening for DITs, and thus DITs may have been included in sample.
4. First 25 unclipped fish landed each day sampled.
5. Clipped and unclipped fish sampled. Samplers told to collect every xth fish, regardless of clip status (X could vary among samplers). In general, sampling was probably representative of the catch sampled. This sampling was part of an intensive sampling program that was separate from the ongoing GSI sampling program. These samples were not used in annual stock composition estimates.
6. Unknown mark status
7. Clipped only fish sampled

2) WCVI Outside Sport

No attempts have been made to provide a representative GSI-based estimate of stock composition of annual catch from the WCVI outside sport fishery. However, some sampling was done in 2002 and 2003 to investigate temporal variability in stock composition in this fishery, though sampling was not representative of the fishery as a whole (Table 6-8). For the most part, such sampling was carried out by creel surveyors, who collected DNA samples primarily from unclipped Chinook.

Table 6-8. Details on GSI sampling of Chinook salmon in the WCVI outside sport fishery from 2002-2003.

Year	Month	Catch Region	Stat Area	No. DNA Samples Collected	No. DNA Samples Processed For Stock Composition Analysis
2002	June 1-23	SWVI	123	46	46
2002	July 1-27	SWVI	123	60	60
2002	August 3-10	SWVI	123	25	25
2003	July	SWVI	123	99	99
2003	August	SWVI	123	93	93

7. For those stocks for which analysis is available, update through 2004, the tables listed in Appendix G of CTC (2004). For all stocks compare average figures for appropriate prior years to average figures for those years (e.g., 1999-2004) for which specific stock concerns influenced the conduct of the NBC and/or WCVI fisheries;

Stock distributions for both reported catch and total mortality are generated as part of the CTC's annual CWT Exploitation Rate Analysis. This section contains data output from the 2006 Exploitation Rate Analysis, with data available through 2004. Only information on distribution of reported catch is presented as changes in distribution patterns for both reported catch and total mortality are similar. Tables 7-2 to 7-5 summarize the distribution of landed catch mortality (expressed in terms of adult equivalents) separately for the WCVI AABM fishery, the WCVI troll fishery alone, the WCVI sport fishery alone, and the NBC troll fishery for stocks that have a non-zero value in any year. Note that WCVI sport includes both outside (AABM) and inside (ISBM) recoveries. This is because for many recoveries, the recovery location information is not specific enough to reliably separate them into inside and outside. Note also that recoveries from the QCI sport fishery are currently rolled up with the rest of the north/central BC sport fisheries. Consequently, recovery information specific to the QCI sport fishery cannot currently be provided. Averages are provided for the following periods:

- 1979-1982: the PST base period.
- 1985-1995: ceiling management regime, total mortality base period, and prior to Canadian actions directed at conservation concerns for WCVI Chinook and coho stocks.
- 1999-2004: management under 1999 Agreement.
- 2002-2004: years when Canadian AABM catch approached allowable limits and temporal distribution of catch changed significantly in the WCVI troll fishery.

For the indicator stocks that represent natural stocks of Canadian domestic conservation concern, the full Appendix G tables are also presented to provide a time series of estimates for the distribution of mortalities among fisheries and escapement (Table 7-6 to 7-8). The natural stocks of Canadian conservation concern are WCVI, Lower Georgia Strait and Fraser Early. The Robertson Creek hatchery stock is the exploitation rate indicator stock for WCVI. The Cowichan and Big Qualicum are exploitation rate indicator stocks for Lower Georgia Strait stocks. No CWT indicator stock is available to represent the Fraser Early stock.

Stocks with zero reported CWT impacts in the NBC or WCVI AABM fisheries or that have chronically poor escapement data are not included. In addition Nisqually FF escapement data may be bad before 1992 and George Adams FF escapement data may be bad before 1993.

Workgroup observations on changes in impacts by stock group are summarized in Table 7-1. It is important to note that the distribution of reported catch data presented is computed as

$$\text{Percent of Total Run} = \frac{\text{Fishery Catch in AEQs}}{\text{Total Catch all Fisheries in AEQs} + \text{Escapement}}$$

and therefore can be influenced by a number of factors unrelated to changes in fishing patterns, including changes in the total fishery catch, changes in the catch of other fisheries, the abundance of the stock in question relative to other stocks intercepted in this fishery, and changes in escapement counting.

Table 7-1. Summary of observed changes of impacts of Canadian AABM fisheries on exploitation rate indicator stocks from 1979 to 2004.

Stock Complex	WCVI AABM (Troll + Outside Sport¹)	NBC AABM (Troll Only)
Alaskan	Not significantly impacted.	No base period data is available. Historic impacts average less than 1%.
North Central BC (Kitsumkalum)	Not significantly impacted.	No base period data is available. Impacts averaged about 8% of the run from 1985-1995 and impacts in 2002-2004 averaged about 3%.
WCVI (Robertson Creek)	The proportion of the total run accounted for by the WCVI AABM fisheries in 2002-2004 (2.7%) is less than 40% of the 1979-1982 average of 7%. The proportion of the total run taken by the WCVI troll fishery from 1979-1982 of 6.5% decreased to 0.2% from 2002-2004, about 3% of the base level.	The proportion of the run accounted for in recent years (1.8%) is less than one-sixth of that observed during the base period (about 11%).
Upper Georgia Strait (Quinsam Fall)	Historic impacts average less than 1%. No impacts observed in recent years.	This fishery accounted for over 10% of the impacts to this stock in the base period. Impacts since 1999 have averaged less than 1%.
Lower Georgia Strait (Puntledge, Cowichan, Big Qualicum)	Impacts observed in 2002-2004 were about the same as those in 1979-1982, for Puntledge and Big Qualicum stocks. Impacts on the Cowichan fall stock has tripled in 2002-2004, compared to 1985-1995.	Impacts have decreased since the base period, and remain relatively small (about 2% or less).
Fraser Early (none)	No information	No information
Fraser Late (Chilliwack)	No base period information is available. Impacts in 2002-2004 average 57% of the rates seen from 1985-1995.	No base period information is available. Impacts have consistently been < 1% since 1985.
Puget Sound Spring Chinook (Nooksack Fingerling, Nooksack Yearling, Skagit Fingerling, Skagit Yearling, White River Yearling)	Base period data are not available for these stocks and a complete time series in recent years is not available for Nooksack Yearlings and White Yearlings. The average proportion of the total run accounted for by reported catch in 2002-2004 exceeds the levels observed in prior years in 5 of 6 cases for Nooksack Fingerlings, 5 of 5 cases for Skagit Fingerlings, and 11 of 11 cases for Skagit Yearlings.	The proportion of the run accounted for by reported catch in this fishery has remained unchanged under PST management. The impact on these stocks is very small (<1%).
North Puget Sound Fall (Skagit Summer, Stillaguamish Fingerling, Nasqually Fingerling, Samish Fingerling)	Base period data are not available for this stock group. For most stocks, the proportion of the run taken by the fishery has not changed since the mid 1980s.	The impact of the fishery on these stocks is small, but has increased slightly since 1999 for the Skagit Summers, averaging about 2% of the run from 2002-2004.
South Puget Sound Fall (SPS Fall Fingerlings, SPS Fall Yearling)	This stock group shows little change in the proportion of the run taken in 2002-2004 compared to the base period or other time periods.	Impacts on this stock group have increased in 2002-2004 compared to the base period and the pre 2002 periods, but remain very small (<1%)
Hood Canal (George Adams)	This stock group shows little change in the proportion of the run taken in 2002/03 compared to the base period or other time periods.	Impacts remain very small (<1%)

Table 7.1 Continued.

Stock Complex	WCVI AABM (Troll + Outside Sport)	NBC AABM (Troll Only)
Washington Coastal Fall (Hoko, Sooes, Queets)	Historically, the reported catch by this fishery accounted for approximately 10% of the run. Impacts have been substantially reduced since 1999. In this stock complex, base period data are only available for the Queets. The proportion of the Queets run accounted for by the WCVI AABM fishery has been reduced from about 12% in the base period to about 1% in 2002-2004.	The reported catch by this fishery accounted for about 16% of the Queets run in the base period and about 12% from 1985-1998, but decreased to about 6% from 1999-2004.
Willamette Spring	The reported catch by this fishery accounted for approximately 4% of the run during the base period. Impacts observed in 2002-2004 are about 3%. Impacts from 1985-1998 were about 2%.	The reported catch by this fishery accounted for approximately 10% of the run during the base period. Impacts have been substantially reduced since 1985 under the PST, and averaged < 1% of the run in 2002-2004.
Columbia River Summer	The reported catch by this fishery during the base period accounted for about 17% of the run. Impacts observed since 2001 have been substantially higher than levels observed from 1994-2000. In 2002-2004, the 14% of the run accounted for by the WCVI AABM fisheries was about 85% of the 1979-1982 base period levels.	The reported catch by this fishery accounted for 8% of the run during 1979-1982, then about 3% of the run from 1985-1998. Impacts observed for 2002-2004 indicate that the reported catch for this fishery represented about 9% of the run, slightly higher than during the base period and 3 times the 1985-1998 impacts.
Columbia River Tule(Cowlitz, Spring Creek, Lower River Hatchery)	The reported catch by this fishery accounted for approximately 16%-25% for these three stock groups prior to 1985. Impacts were reduced in response to PST regimes from the mid-1980s to late 1990s. Impacts observed in 2002-2004 were above the levels observed since 1985 and range from 59% to 96% of 1979-1982 base period averages, for these three stocks.	The reported catch by this fishery accounted for a small proportion of the run during 1979-1982. Impacts observed for 2002-2004 indicate that the proportion of the run accounted for by this fishery has not changed significantly under the PST.
Lewis River Fall	The reported catch by this fishery accounted for about 6% of the run during the base period. Average impacts since then have been similar, about 7% from 1985-1995 and about 8% from 2002-2004. Impacts were estimated at 0% from 1996-2000.	This fishery has had a light impact on this stock throughout the time series, averaging about 3% of the run from 1981-1998, and then averaging less than 2% since 1999.
Columbia River Bright	The reported catch by this fishery accounted for about 7% of the run in 1979-1982 but increased to an average of about 9% from 1985-1995. Impacts have been substantially reduced under the PST since the mid 1990s and were estimated to average about 2% in 2002-2004.	The reported catch by this fishery accounted for approximately 6% of the run in 1979-1982. Impacts observed in 2002-2004 averaged about 3% of the run, about one-half the level observed during the base period.
Snake River Fall	CWT data for this stock are very limited. Average impacts of 2.6% in 2003-2004 were about one-fifth of those observed from 1985-1994.	Impacts in 2003-2004 averaged about 1% of the run, and were less than one-quarter (25%) of the average impact observed from 1986-1994.
Salmon River (Oregon Coast) Fall	The reported catch by this fishery accounted for about 6% of the run during the base period and the average remained relatively unchanged for the period of 1985-1995. Average impacts were reduced to less than 1% since 1995 with no year since exceeding 2%.	The reported catch by this fishery accounted for about 21% of the run during the base period, then dropped to average of about 12% from 1985-1995, and subsequently dropped again to an average level of about 5% from 2002-2004.

¹ In many cases, CWT recoveries from the WCVI sport fishery cannot easily be identified as 'outside' (AABM) or 'inside' (ISBM), due to uncertainty in the recovery location. Consequently, the percentages reported here for the WCVI AABM fishery reflect CWTs recovered in all WCVI sport fisheries (the exception is Robertson Cr. sport recoveries, which do not include recoveries from Albemni Canal, i.e. terminal recoveries). Most recoveries of non-local stocks would occur in the outside sport fishery.

Table 7-2. Percent of total run (reported catch and escapement, measured in terms of adult equivalents) for PST Chinook CWT indicator stocks taken in the WCVI AABM (sport and troll sectors combined¹) fishery. Bold font depicts values for indicators associated with stocks of Canadian domestic conservation concern. Blank cells indicate a gap in tagging.

¹ In many cases, CWT recoveries from the WCVI sport fishery cannot easily be identified as 'outside' (AABM) or 'inside' (ISBM), due to uncertainty in the recovery location. Consequently, the percentages reported here for the WCVI AABM fishery reflect CWTs recovered in all WCVI sport fisheries (the exception is Robertson Cr. sport recoveries, which do not include recoveries from Albemarle Canal, i.e. terminal recoveries). Most recoveries of non-local stocks would occur in the outside sport fishery.

² Troll catch is by calendar year from 1979-1998 and troll accounting year from 1999-2005. Also, note that sport harvest data not available prior to 1992 and harvest for 1979-1991 is troll only.

Table 7-3. Percent of total run (reported catch and escapement, measured in terms of adult equivalents) for PST Chinook CWT indicator stocks taken in the WCVI troll fishery. Bold font depicts values for indicators associated with stocks of Canadian domestic conservation concern. Blank cells indicate a gap in tagging.

¹ Troll catch is by calendar year from 1979-1998 and troll accounting year (previous October to September of the current year) from 1999-2005.² Amount based on post-season allowable catch, i.e. total post-season allowable AABM catch less outside sport catch.

Table 7-4. Percent of total run (reported catch and escapement, measured in terms of adult equivalents) of PST Chinook CWT indicator stocks taken in the WCVI sport¹ fishery. Bold font depicts values for indicators associated with stocks of Canadian domestic conservation concern. Blank cells indicate a gap in tagging.

¹ In many cases, CWT recoveries from the WCVI sport fishery cannot easily be identified as 'outside' (AABM) or 'inside' (ISBM), due to uncertainty in the recovery location. Consequently, the percentages reported here for the WCVI AABM fishery reflect CWTs recovered in all WCVI sport fisheries (the exception is Robertson Cr. sport recoveries, which do not include recoveries from Albemni Canal, i.e. terminal recoveries). Most recoveries of non-local stocks would occur in the outside sport fishery.

² Sport catch is generally not managed to a target, and therefore is always considered to have achieved its full allocation.

Table 7-5. Percent of total run (reported catch and escapement, measured in terms of adult equivalents) of PST Chinook CWT indicator stocks taken in the NBC troll fishery. Blank cells indicate a gap in tagging.

²¹Represents both inside and outside sport.

8. Provide annual stock compositions through 2004 for the WCVI and NBC fisheries as in Appendix I of TCCHINOOK(04)-4, again with average figures calculated for appropriate prior years compared with average figures for those years for which specific stock concerns influenced the conduct of the NBC and WCVI fisheries;

The PSC Chinook Model serves as the data source for Appendix I; however, because the model operates under base period exploitation patterns and stock distribution, model-generated estimates of stock composition would not be expected to be representative of those resulting from the different fishing patterns observed in recent years.

Table 8-1 contains estimates of stock composition generated by the 2005 calibration (#0506) of the PSC Chinook Model for the WCVI AABM fishery complex. Tables 8-2 and 8-3 show the estimated stock composition for the WCVI troll and sport fisheries separately. The five stocks with the largest stock composition estimates in the base period from 1979-1982 for the WCVI AABM fishery complex were: 1) Fraser Late at 24.3%, 2) Spring Creek Hatchery at 14.0%, 3) Nooksack Fall at 9.3%, 4) Bonneville Hatchery at 10.5% and 5) Cowlitz Fall at 8.5%. Considerable variation in stock compositions is evident, reflecting interannual variability in relative stock and cohort strengths.

Table 8-4 contains estimates of stock composition generated by the 2005 calibration (#0506) of the PSC Chinook Model for the NBC AABM fishery complex. Table 8-5 shows the estimated stock composition for the NBC troll fishery separately. No separate table is shown for the sport fishery as no base period data exists for the QCI fishery alone. Rather, the base period used by the model for this fishery consists of all north and central BC sport fisheries data; this introduces some bias into the stock composition estimates shown in Table 8-4 for the NBC AABM fishery as a whole, regardless of any changes in fishing patterns. Consequently, only the troll fishery should be used to assess changes in stock impacts using model data. The eight stocks with the largest stock composition estimates in the base period from 1979-1982 for the NBC troll fishery were: 1) Oregon Coast Fall at 26.3%, 2) CR URBs at 8.4%, 3) NCBC at 8.2%, 4) WCVI Hatchery at 6.8%, 5) Willamette Hatchery at 6.1%, 6) WA Coastal wild at 6.0%, 7) Fraser Early at 5.7% and 8) Upper Georgia Strait at 5.6%. Considerable variation in stock compositions is evident, reflecting interannual variability in relative stock and cohort strengths.

Tables 8-6, 8-7 and 8-8 provide model estimates of the percent of total run (in catch + escapement) of stocks accounted for by the WCVI AABM fishery complex. Tables 8-9 and 8-10 provide the same estimates for the NBC AABM fishery complex and the NBC troll fishery, respectively. These tables were provided for the potential comparison of the percents from the coded-wire tag analysis data, e.g., Appendix G data from CTC (2004).

Table G-1. Stock Composition of the WCVI AABM fishery (Troll and Sport) as estimated from the PSC Chinook Model (CLB-0506) for calendar years 1979-2004.

9. For the NBC and WCVI fisheries, provide the CTC's assessment of the GSI data that supports the presentations referenced in assignment 2 above and the stock-specific management plans, and detail how that data may be utilized in advancing our understanding of stock composition in those fisheries;

John Candy from the Molecular Genetics Laboratory at the Pacific Biological Station of the Department of Fisheries and Oceans met with the Workgroup on November 16, 2005, to review the data and methodology used to generate GSI estimates. DFO provided extensive documentation to the Workgroup (Appendix 2).

Our evaluation will be divided into the following categories:

1) description of the baseline, 2) power and accuracy of the baseline, 3) mixture estimations, 4) comments on PowerPoint presentations, and 5) conclusion and recommendations

Many of the comparisons will be to the standardized microsatellite baseline recently developed by the *Genetic Analysis of Pacific Salmon* (GAPS) group using funding received from the Pacific Salmon Commission U.S. Letter of Agreement and administered by the U.S. PSC commissioners.

1. Description of DFO baseline

DFO submitted a baseline that was likely representative of the baseline actually used, but was not identical. The baseline used in any particular mixed stock analysis varied depending on the year when the analysis occurred as well as the particular analysis. Likewise the regions reported also differed depending on the analysis. The DFO baseline was built on a set of 13 microsatellite loci (see Appendix 2). The number of alleles per locus varied from 12 to 54 and averaged 30 alleles per locus with a total of 386 alleles across all loci. The amount and distribution of variation is typical of Pacific salmon microsatellite databases and, given appropriate baseline and mixture sample sizes, should provide adequate resolution for a broad range of questions. By comparison, the GAPS baseline also includes 13 loci with an average of 37 alleles per locus.

The baseline was composed of populations ranging from Central California (Sacramento River) through Southeast Alaska (Alsek drainage) and included 240 populations divided into 33 (or 34 in some analyses) regional groups. Most of these populations were collected in multiple years dating from the early 1990's through early 2000's. Results from the 33 (or 34) regional groups were pooled into 14 larger reporting regions for the pie diagrams in the PowerPoint presentations. The baseline was uneven both in terms of number of individuals and number of populations in the reporting groups. Across the regions, the number of individuals varied considerably from a high of 4,861 from WCVI to a low of 99 from Juan de Fuca (Figure 9-1). Of the 240 populations, 36 (13%) had sample sizes below 50. Individual population sample

sizes varied considerably from a high of 899 (Puntledge) to a low of 22 (Goldstream). Small sample sizes will result in a reduction in the accuracy and precision of estimates of allele frequencies as well as the ability to detect the presence/absence of all alleles, so estimates based on small baseline sample sizes should be interpreted with caution.

A single Canadian laboratory developed the baseline, and both the number of individual fish and populations were heavily weighted towards Canada. Individual fish from Canadian stocks composed over 80% of the baseline with 35,400 individuals followed by U.S. (including Alaska) with approximately 6,000 (13%), and Transboundary individuals totalling approximately 2,700 (7%). Some of the U.S. regions that had the largest sample sizes include the Central Valley Fall of California and Snake River Spring and Summer, regions that are not likely to contribute heavily to WCVI fisheries. The Lower Columbia region, estimated to contribute between 40-60% of the fish in many time periods, was represented by only 266 fish. Puget Sound stocks, also large contributors in some strata, were better represented with 960 individuals from nine populations in the baseline. Given the overall under representation of U.S. stocks in the baseline, there may be a systematic bias in the estimates. The magnitude and direction of the bias will likely depend on the composition of the mixture and the allele frequency differences among the contributors to the mixture (Wood et al. 1987).

By contrast, the GAPS Version 1.0 of the baseline includes higher representation of U.S. both in number of populations and sample sizes. Of the 16,000 individuals, 34% originated from Canadian populations, 7% from Transboundary populations, and 59% from U.S. populations.

Sample sizes of many of the populations included in the baseline are below the target sample sizes of 144 set by the GAPS group. Both empirical and theoretical data were used to set the target. The GAPS baseline Version 1.0 had 4% of populations below 50.

2. Power and accuracy of the baseline

DFO submitted an analysis of CWT fish as a test of the accuracy of the baseline. The analysis used a Bayesian method for stock estimation. With this method, some uncertainty in baseline allele frequencies can be accounted for in the estimation process. The evaluation was based on 306 CWT Chinook salmon that were sampled from fisheries in British Columbia during 1997 (Appendix 2, Figure 9-1) and from 297 fish sampled from a troll fishery off the southwest coast of Vancouver Island in 2001 (Appendix 2, Figure 2). The evaluation used a somewhat different baseline from that used in the 2003/2004 estimates provided. The evaluation baseline included 52,000 fish from 325 populations distributed from throughout the range of Chinook salmon including Russia and Northwest Alaska and estimated 45 reporting groups. It is likely the majority of new individuals originated from the additional coverage, but this could not be determined from the information provided. Reporting groups for the Southeast Alaska to California regions were condensed somewhat with only a single Lower Fraser group and pooling of the Lower Columbia and Willamette groups into a single group.

This resulted in 31 instead of 33(34) groups. Despite inconsistencies between the baseline actually used and that submitted for evaluation purposes, some trends are apparent.

Figure 1 in Appendix 2 represents a complex mixture of Southeast Alaska, British Columbia, and southern US stocks. Canadian regions that were well represented in the baseline (Northern BC Mainland $N > 3,500$, Skeena $N > 3,100$, Lower Fraser $N > 1,500$) are overestimated as is Puget Sound ($N > 930$). Regions with smaller sample sizes that were underestimated include Southeast Alaska ($N > 350$) and Central Valley Spring ($N > 150$). Two regions, Oregon Coastal ($N > 740$) and Middle Fraser ($N > 4,350$) were also underestimated despite having what appear to be large sample sizes. In the case of the Oregon Coastal region, additional diversity may exist that is not adequately represented by the included populations. For Middle Fraser, the baseline may not sufficiently differentiate it from other regions (e.g., Lower Fraser was overestimated).

Figure 2 in Appendix 2 represents a much simpler mixture with both the true and estimated proportions nearly 60% Puget Sound individuals. The Lower Columbia/Willamette and Upper Columbia Su/F were overestimated while the Snake Fall group was underestimated.

3. Fishery Mixture Samples

The Workgroup was provided with estimates for the following fisheries:

	Area	Date	N screened
Periodic Sampling			
		2003	
	Area123-10	Nov	72
	Area123-10	Dec	72
		2004	
	Area23	January	100
	Area123/23	February	99
	Area23	March	100
	Area126	March	100
	Area123	April	100
	Area126	April	100
	Area126/127	April	99
	Area123	May 1-3	99
	Area124	May 15-16	96
	Area125-127	May 15-16	101
	Area126	Sep-21	100
Intensive Sampling			
		2004	
	A123-13	May	328
	A123-12/13	May	330
	A123-12(few 13)	May	190
	A126	May	140

Stock proportions and standard deviations were estimated using a Bayesian analysis. Estimates were provided for 33 regions for the periodic sampling and 34 regions for the intensive sampling. A Sacramento group was included in the intensive sampling in addition to the two Central Valley groups. It was not possible to determine how the populations were assigned to the 34 groups relative to the assignments in the 33-group analysis. Sample sizes were small for the periodic sampling ranging from 72 to 101 individuals. Sample sizes were considerably larger for the intensive sampling ranging from 140 to 330 individuals.

The small sample sizes of the periodic sampling greatly decrease the precision of the estimates relative to the intensive sampling estimates. This can be seen in the relatively large standard deviations for the periodic sampling. The resulting confidence intervals are large, so only major trends can be extrapolated from the periodic sampling. In many cases, the confidence intervals included zero, so even the presence or

absence of a stock could not be reliably determined. A much higher level of confidence can be attributed to the intensive sampling estimates.

Decisions on sample sizes should be based on the desired level of accuracy and precision balanced against limitations of sample availability and funding. Marlowe and Busack (1995) conducted a bootstrap power analysis using the 25 stock Coastal troll Chinook fishery in Washington State. Their study suggested a minimum mixture sample size of 200 would be necessary to detect stocks contributing at rates of 5% or higher, using the electrophoretic baseline in use at the time. Increasing the mixture sample size improves both the detectability of smaller contributions and the reliability of contribution estimates.

Caution is required if GSI estimates are to be used in expansions to estimate the number of individual populations in the catch, particularly if the stock of interest represents a small proportion of catch. Further discussions on this issue are included in the Report of the Expert Panel on the Future of the Coded Wire Tag Recovery Program for Pacific Salmon. For the GAPS baseline, a power analysis is currently being conducted using LOA funds secured in FY06. As part of that analysis, the Panel recommended that methods be developed to determine the appropriate sample sizes for various mixtures and as a function of the desired accuracy and precision of the statistic of interest.

4. Comments on PowerPoint Presentations

The numerous pie diagrams presented within the various PowerPoint presentations are useful to visualize variability in stock composition estimated from small sample sizes taken from highly mixed stock fisheries. The Workgroup evaluated only the 2003/2004 fishery samples, so the majority of the analyses depicted in the pie diagrams could not be evaluated. The reporting regions varied considerably, sometimes at the same fine-scale level as the 33 regions evaluated here; at other times the estimates were pooled into larger regional groups. For example, "Puget Sound" and "Washington Coast" were shown both independently but also pooled into "Washington." As a general comment, the compositional estimates for larger reporting regions will likely have improved precision and accuracy for a given sample over estimates of the proportion of the catch comprised of an individual stock. However, no indication or depiction of the precision of any of the estimates was given. To an audience unfamiliar with GSI studies, this can lead to a misleading sense of the precision of the estimates, of particular concern with smaller mixture sample sizes such as those used in the 2003/2004 periodic samples.

5. Conclusions and Recommendations

The Workgroup evaluated the 2003/2004 baseline estimates for its coverage both in terms of number of populations and individuals. The baseline, although cumulatively composed of a large number of individuals, was skewed towards Canada both in the number of individuals and populations. Within the US populations, there was an uneven distribution among populations and regions. Thus, there may be a bias in the

estimates. The magnitude and direction of any bias would depend on the composition of the mixture under investigation.

The Workgroup evaluated estimates from periodic and intensive sampling of the WCVI fishery for 2003/2004. The sample sizes for the periodic estimates were small, averaging less than 100 individuals. This resulted in large confidence intervals around all the estimates. The estimates are best used as indicators of trends or relative contribution. They shouldn't be used to extrapolate to numbers of individuals harvested without a great deal of caution. The intensive sampling in May of 2004 had larger sample sizes and a considerably higher level of precision and would be more appropriate for a variety of analyses.

The Workgroup through the LOA funds has invested heavily in developing a standardized DNA database by the GAPS (including DFO) group. The GAPS baseline has representation of all the major U.S. and Canadian lineages from the PSC area of interest and is continuing to grow. As such, it is more balanced than the DFO baseline, and more appropriate for PSC applications. The GAPS group has also been funded to conduct comprehensive power analyses and develop mixture and sampling guidelines. The use of GAPS baseline and sampling guidelines would reduce controversy over interpretation of results in studies reporting GSI-based estimates of stock composition for the PSC.

Figure 9-1. Number of individuals in each of 33 regions in the DFO GSI baseline for Chinook salmon.

10. After the tasks listed above have been completed, outline, in a separate document if necessary, technical difficulties for implementation of the agreed AABM fishery regimes that may be created by fishery patterns that change (possibly in-season) in order to alter the exploitation rates on specific stocks. Include any recommendations for monitoring programs and for analytical methods to estimate stock-specific impacts (across the range of stocks in an AABM fishery) that may result from such alteration in the conduct of a fishery.

The requested recommendations in Assignment 10 could only be addressed after the other tasks had been completed, and scrutinized by the Workgroup. Additional analyses were completed since the previous draft of this report in an attempt to address this assignment. These are presented below. Note that the expert panel has previously commented on the above topic as well (see Appendix 1).

Fishery Indices

The Workgroup compared fishery indices (reflecting relative changes in fishery harvest rates) for the WCVI and NBC troll fisheries derived from the CWT exploitation rate analyses with the index estimated by the PSC Chinook Model. For the WCVI troll fishery, a different picture emerged. Prior to 2000, the two indices were closely correlated. Since then, however, the indices have diverged. The Model-based fishery indices since 1999 indicate that the relative harvest rate has been below the target level anticipated under the 1999 Chinook agreement. In contrast, the CWT-based estimates are well above the target level since 2000 (Fig 10-1), while for the NBC troll fishery, the model indices have been higher than the CWT indices since 2002 (Fig 10-2).

The change in timing of the catch by the WCVI troll fishery has been a source of concern for the CTC and Southern U.S. fishery managers. The deviation of the CWT and fishery indices reinforces this concern. The Workgroup has proposed a method to improve the capacity of the PSC Chinook model to account for temporal changes in the conduct of the WCVI troll fishery.

Figure 10-1. Estimated CWT (through 2004) and PSC Chinook model (through 2005) landed catch fishery indices the WCVI troll fishery, from the 2006 PSC Chinook model calibration.

Figure 10-2. Estimated CWT (through 2004) and model landed catch fishery indices (through 2005) for the NBC troll fishery, from the 2006 PSC Chinook model calibration.

To address part of Assignment 10, the Workgroup investigated the utility of two additional analyses to attempt to address the question of whether changes in the conduct of the WCVI and NBC troll fisheries have differentially impacted some stocks more than others. The Workgroup concluded that significant changes have not occurred in the NBC troll fishery and limited further work to the WCVI troll fishery. Analysis 1 examines how model stock composition can be affected by changes in

temporal fishing patterns and regulations (see Section 10 below). Analysis 2 involves the development of a standardized index to reflect changes in the concentration of recoveries of selected CWT-marked stocks in two time periods, pre-1999, and 1999-2004.

Analysis 1: A model-based method to analyze effects of changes in the timing of catch on stock composition.

Introduction

This analysis illustrates how stock composition can be affected by fishing patterns and regulations. Two types of analyses are presented. The first provides insight into how stock compositions can vary by month. The second show four examples of how annual stock compositions can change depending on the timing of the catch and minimum size limits. We performed the analysis only for the WCVI troll fishery, as the fishing patterns for the NBC troll fishery were comparatively stable.

Method

The method utilizes the annual stock-age-specific base period exploitation rates employed by the PSC Chinook Model. These annual exploitation rates are apportioned in accordance with the percentage of the total recoveries taken in a given month.

For each fishery, individual CWT recovery records were stratified by month and ocean age for the same CWT release groups that are used to generate the base period exploitation rates. The percent base period CWT recoveries by month were computed by stock and age¹:

$$\frac{CWT_{s,a,f,m}}{\sum_m CWT_{s,a,f,m}} \quad (1)$$

The percent recoveries were then used to apportion the base period annual exploitation rate (BPER) by month to derive monthly base period exploitation rates:

$$BPER_{s,a,f,m} = \frac{CWT_{s,a,f,m}}{\sum_m CWT_{s,a,f,m}} * BPER_{s,a,f} \quad (2)$$

The monthly base period exploitation rates were divided by base period reported catch to obtain the exploitation rate on a per fish basis:

$$\frac{BPER_{s,a,f,m}}{BPCatch_{f,m}} \quad (3)$$

¹ For some model stocks, the exact CWT release groups used to generate the BPERs could not be determined. Except for Snohomish summer/fall stock, the CWTs listed in the 1991 CTC Model documentation were used. For Snohomish stock, recoveries from the 1971 through 1976 brood year fingerling releases of progeny of local broodstock were used.

For a given year (or combination of years) y , the percent catch for each month was estimated:

$$\frac{Catch_{y,m}}{\sum_m Catch_{y,m}} \quad (4)$$

The BPER per fish (Eq. 3) and the percent catch by month (Eq. 4) were multiplied by the base period catch in each fishery to estimate the monthly exploitation rates that would have been observed for base period catches under the fishing pattern in year(s) y and base period stock distribution:

$$NewBPER_{s,a,f,m} = \frac{BPER_{s,a,f,m}}{BPCatch_{f,m}} * \frac{Catch_{y,m}}{\sum_m Catch_{y,m}} * BCatch_f \quad (5)$$

The effect of changes in the timing of the catch and size limits on stock compositions is evaluated using equations (6) and (7). Equation 6 computes the catch that would have occurred for CTC model stocks under the fishing pattern for month m :

$$NCatch_{f,m} = \sum_s \sum_a NewBPER_{s,a,f,m} * N_{s,a} * PV_{a,f} \quad (6)$$

Where $N_{s,a}$ = the base period cohort size for stock s and age a and $PV_{a,f}$ is the proportion of a cohort of age a that is above the minimum size limit for fishery f .

Equations (7) and (8) simply compute the composition of the catch that is comprised of fish from a given stock group. This method does not reflect potential implications of changes in stock distribution.

The percent contribution of a stock or stock group is estimated as follows for stocks s in group g for month m :

$$StkComp_{g,m} = \frac{\sum_{s \in g} \sum_a NewBPER_{s,a,f,m} * N_{s,a} * PV_{a,f}}{NCatch_{f,m}} \quad (7)$$

These monthly stock compositions are shown in Figure 10-3. Annual percent stock or stock group is also estimated for year(s) y :

$$StkComp_{g,y} = \frac{\sum_{s \in g} \sum_a \left(\sum_m NewBPER_{s,a,f,m} \right) * N_{s,a} * PV_{a,f}}{\sum_m NCatch_{f,m}} \quad (8)$$

These stock composition estimates for individual stocks over a range of years with similar regulations are shown in Figure 10-4 through Figure 10-7 and can be directly compared with those from the CTC Model.

Results

The analysis outlined above can be used in a number of ways to examine the potential effects of changing temporal fishing changes in catch patterns and minimum size limits. Since these analyses are based on model base period abundances, it should reflect seasonal availability of stock groups to the fishery, independent of fluctuations in stock size. It is important to remember that these data are based primarily on CWT sampling during the 1979 – 1982 base period.

Caveats, cautions, and assumptions:

- 1) If catch during a particular month in the base period was small, or not adequately sampled for CWTs (as could have occurred in March or Nov/Dec of the base catch years), results will not be as reliable as those from months with larger catch or more intensive sampling. In addition, for some stocks, CWT recovery data used to generate base period exploitation rates were collected during years in which fishing may not have occurred in some months. For example, if CWTs for a stock were collected during a period when fishing only occurred during the summer, there would be no recoveries during other months. This can lead to anomalous results. For example, the data in Table 10-1 show that in March, October, and November, only Columbia River and Puget Sound stocks are present in the WCVI fishery, which is extremely unlikely. A more reasonable interpretation of the information might be that those stocks represent the majority of the catch, with other stock groups making lesser contributions. Nonetheless, the error introduced by "out of base" stocks in the model is not believed to be substantial; variability in monthly stock compositions are likely true reflections of relative differences in the availability of individual stocks.
- 2) The data in this analysis are from the PSC Chinook model only and are restricted to CWT recovery data used to generate stock-age-fishery specific exploitation rates, generally for the period from the 1979 – 1982 base period. As such, the results are not directly comparable, stock by stock, to the CWT data presented in Section 7 of this report.
- 3) Only stocks included in the PSC Chinook model are included in this analysis. Absence of a stock or stock group from this analysis does not necessarily demonstrate lack of impact on that stock. It may only mean that the stock is not included in the model. A complete list of stocks included in the model is provided in Table 10-2.
- 4) The distribution of stocks is assumed to remain constant in this analysis, i.e., recent stock movement and migration patterns are assumed to be the same as those observed in the 1979-1982 base period.
- 5) Recent relative stock abundances are also assumed to be the same as those observed during the base period; this allowed us to isolate the effect of changes in temporal distribution of catch and minimum size limits on stock-specific exploitation rates.

Table 10-1 and Figure 10-3 illustrate how monthly stock compositions can be expected to change during the base period. For example, Figure 10-3 shows that Columbia River stocks should on average contribute heavily to the WCVI troll catch early in the season, from March to June, then at a relatively steady rate, 20 – 40 % of the total catch, for the

remainder of the year. Puget Sound stocks, on the other hand, comprised less than 25 % of the catch from March through August, and then increased in September. The Fraser River stocks show a strong pattern of increased contribution to the WCVI catch from March to a maximum in July of 55 percent; contribution then decreased as the season progressed.

Table 10-1. Monthly stock composition of the WCVI troll fishery under base period stock abundances, temporal fishing patterns and size limits.

Figure 10-3. Average monthly stock composition of the WCVI troll fishery under base period stock abundances, temporal fishing patterns and size limits (1979-1982).

Table 10-3 and Figure 10-4 show how the model base period catch stock composition of the major stock groups in the WCVI troll fishery would have changed across several time periods since 1982, representing differing temporal distribution of catch, magnitude of catch, minimum size limits, or a combination of these factors. The distribution of catch by month during each period is shown in Table 4-4. During the 1979-1982 base period, fishing generally occurred from March to December, with catches averaging over 400,000 annually. The size limit during the base period was 66 cm. The 1987-1995 fishing period was characterized by declining catches, ranging from approximately 400,000 in 1987 and 1988 to under 100,000 in 1995. Fishing generally occurred from May to September, with a size limit of 67 cm. From 1999-2001, catches averaged about 50,000 fish per year, with fishing occurring March – May and September – December. During this period, no fishing occurred in June, July, or August and very little occurred in September. The size limit was 55 cm. In 2002-2004, the average catches increased from the previous period to approximately 150,000. While fishing continued to occur primarily during the spring and fall months, significant fishing also occurred in June and September. The size limit remained at 55 cm.

In considering the results of this analysis, it is important to remember that the stock compositions presented are not observed stock compositions, but are those that would have been generated by the model if all four periods fished on the same stock abundances (base period abundances assumed in all cases). Actual stock composition of a fishery catch is influenced by many factors, including relative stock abundance, which will vary annually.

The proportion of Fraser stocks in the WCVI troll fishery in the last two time periods, when most fishing occurred in the spring and fall, is much less than the earlier periods when most catch occurred during the summer months. This result is consistent with the data in Table 10-1, which shows that Fraser stocks would contribute most to fisheries occurring during the summer. Similarly, the WCVI fall stock impacts under fishing periods when fishing occurred primarily in the spring and fall are estimated to be about half of the impacts that would occur with summer fisheries. Puget Sound stocks show a somewhat variable response to temporal variation in fishing. Under the pattern seen in 1999-2001, impacts are predicted to be more than double those observed during the base period. However, the proportion of Puget Sound stocks that would be caught under most recent fishing patterns (2002-2004) is near observed base period levels. The proportion of Columbia River stocks decreases when fisheries occur primarily during the summer months, as occurred from 1985-1997, and increases when the fishery is concentrated in the spring and fall months. Figure 10-5 shows the relative change from the base for the major stock groups for each of the fishing periods.

Figure 10-5. Expected relative change in estimated stock composition in the WCVI troll fishery during fishing periods with differing temporal catch distribution, assuming base period stock abundances and distributions.

Table 10-4 and Figure 10-6 show how the model base period catch stock composition of Columbia River stocks would have changed under the different temporal fishing patterns. Fishing patterns like those observed in 2002 – 2004, with the largest catches occurring in April and May, are predicted to have much less impact on Upriver Bright and Snake River Wild stocks compared to fishing periods in which fishing occurred primarily during the summer and fall months.

Table 10-4. Expected WCVI troll composition of Columbia River stocks during fishing periods with differing temporal catch distribution, assuming base period stock abundances and distributions.

Figure 10-6. Expected WCVI troll composition of Columbia River stocks during fishing periods with differing temporal catch distribution, assuming base period stock abundances and distributions.

Table 10-5 and Figure 10-7 show how the model base period catch stock composition of only the stocks originating in Puget Sound would have changed under the different temporal fishing patterns. Within this stock group, the relative impacts on individual stocks do not seem to change substantially as fishing patterns change for most stocks. The exception is the Snohomish stock, which shows much greater impacts under a fishing period like that observed in 1999-2001 compared to the other fishing periods.

Modification of PSC Chinook model inputs to account for temporal changes in fishing patterns.

A result of the analysis presented above is a straightforward method of adjusting the model stock specific exploitation rates to account for changes in temporal fishing patterns through the use of stock specific FPs.

From above, a new annual exploitation rate by stock and age based on an observed temporal fishing pattern is estimated in equations 5 and 6:

$$NewBPER_{s,a,f,y} = \sum_m \left(\frac{BPER_{s,a,f,m} * Catch_{y,m} * BCatch_f}{BPCatch_{f,m} \sum_m Catch_{y,m}} \right) \quad (1)$$

The general equation used in the PSC Chinook model to estimate catch is

$$Catch_{s,a,f,y} = Cohort_{s,a,f,y} * PV_{a,f,y} * BPEXPRate_{s,a,f,y} * FP_{s,a,f,y} \quad (2)$$

Where

a = age

$BPEXPRate_{s,a,f,y}$ = Model base period observed Exploitation Rate on the vulnerable cohort

$Catch_{s,a,f,y}$ = model predicted catch

$Cohort_{s,a,f,y}$ = stock cohort size

f = fishery

$FP_{s,a,f,y}$ = A scalar that can be used to adjust the BPEXPRates on a stock and age specific basis

$PV_{f,y}$ = Proportion of the cohort at age that is above the minimum size limit

y = year

If the FP in the above equation is defined as

$$FP_{s,a,f,y} = \frac{NewBPER_{s,a,f,y}}{BPEXPRate_{s,a,f,y}} \quad (3)$$

then equation (3) can be substituted into equation (2) and we get

$$Catch_{s,a,f,y} = Cohort_{s,a,f,y} * PV_{f,y} * NewBPER_{s,a,f,y} \quad (4)$$

which reflects the stock catches that would occur under the new temporal fishing pattern.

The CTC intends to explore the potential use this modification of the FPs next year to more accurately model the WCVI troll fishery. This modification should result in more accurate abundance index predictions and more accurate stock specific impact predictions and will be useful in both PSC and domestic management. In future years, the CTC should develop stock specific FPs for the WCVI troll (and other fisheries) using observed CWT recovery data similar to the SPFI in current use for the SEAK troll fishery.

Analysis 2: Changes in Coded Wire Tag Concentration Indices for Stocks in Five Ocean Fisheries for 1979-2004.

Introduction

The Workgroup developed an index that reflects relative changes in encounter rates for individual stocks that were present in the NBC and WCVI troll fishery catches. Raw recoveries alone do not necessarily provide an accurate representation of whether a stock is being encountered more or less frequently in fishery catch. The number of stock-specific CWTs encountered in a fishery will vary with brood year survival and release numbers, as well as the total number of fish landed, all else being equal. The concentration statistic (equation 1), used in development of the index, represents an attempt to adjust recoveries to account for these variables and allow more meaningful inter-annual comparisons of individual stocks that contribute to a fishery catch. By accounting for release numbers, brood year survival, and catch levels, any changes in the concentration index can then be attributed to one or more of the following confounded factors:

1. Changes in the temporal and spatial conduct of the fishery.
2. Changes in fishery regulations, such as size limits.
3. Changes in stock distribution.
4. Changes in survival and abundance relative to other stocks.

It is impossible, however, to determine which confounded factor, or combination of factors, has caused the change in the index.

Tests were conducted to determine if there were statistically significant differences in average values of these indices between two time periods, 1979-1998 and 1999-2004. The latter period roughly represents the years during which some significant changes occurred in the conduct of Canadian AABM troll fisheries, in response to conservation concerns for some domestic stocks, as well as to provide better economic opportunity for fishers. The former period was used to represent a 'base' period. It was thought that these indices would provide quantitative measures of how stock encounters have changed in these fisheries between these two periods. We also examined several

fisheries other than the WCVI and NBC troll, including the SEAK troll, Georgia St. sport and Washington/Oregon (WA/OR) troll. These other fisheries were thought to be more stable over time than the two Canadian troll fisheries, while intercepting stock groups similar to one or the other Canadian AABM fishery, and therefore might provide insights into the underlying causes of any observed changes in index values.

Methods

The Workgroup analyzed coded wire tag-recovery data from adipose-clipped Chinook caught from the years 1979 to 2004 (the data used for the 2005 Exploitation Rate Analysis).

A concentration statistic (p) representing stock contribution to a fishery was computed as follows:

$$p_{s,t} = \sum_{a=3}^{a=5} \frac{E_{s,t,a}}{S_{s,t-a} R_{s,t-a} C_t} \quad (1)$$

where t is the current year of recovery (from 1979 to 2003, and for some stocks, to 2004), $E_{s,t,a}$ is the estimated number of recoveries by stock (s), age (a) and time (t) (i.e., the observed tag recoveries adjusted for sampling rate) in a fishery, S_{t-a} is the associated brood year survival index (from CWT analysis) for stock (s) and age (a), $R_{s,t-a}$ is the number of releases for brood year ($t-a$) and stock (s), and C_t is the catch associated with that fishery in year (t).

The annual concentration index (I) is the concentration statistic scaled to the average value of the concentration index for a stock from 1979-1999, and is calculated as:

$$I_{s,t} = \frac{p_{s,t}}{\frac{\sum_{y=1979}^{1999} p_{s,y}}{n}} \quad (2)$$

where n is equal to the number of valid years where data is available from 1979-1998.

Data Selection Criteria Used in Calculating the Concentration Statistic

Only ages 3, 4 and 5 were used as very few other ages were recovered in these fisheries. In some years all three ages were recovered, while in other years recoveries were observed for only 2 of the age classes.

In addition, only recovery data for a stock from a given brood year were used if there were more than 10 estimated tag recoveries over all ages (3-5) in that fishery. This restriction was implemented to help reduce the occurrence of extreme index values related to small numbers of recoveries alone. However, for Robertson Creek Hatchery and Salmon River Hatchery, estimated tag recoveries were used for 1999 on,

regardless of the number of recoveries, in the WCVI troll fishery only. This 10 tag restriction was relaxed for Robertson Creek because the WCVI troll fishery was deliberately shaped to avoid encounters of this stock in recent years, and thus low recoveries were more likely related to the shaping of the fishery rather than a change in stock abundance or distribution. Salmon River Hatchery fish have historically been encountered in large numbers in this fishery; and since post-1999 recoveries in other fisheries continued to remain strong, it was assumed that low numbers of recoveries of this stock in the WCVI troll fishery were a true effect and could possibly be explained by a change in fishery structure or a change in stock distribution.

Years in which the catch in a fishery was less than 10% of the average catch from 1979 to 2003 were excluded from the analysis of that fishery. This occurred in 1996 and 1998 for WCVI troll, and 1996 for NBC troll. In addition, the year 1999 was excluded from the WCVI analysis because catch for that year occurred exclusively in October, and thus was not thought to be representative of typical fishing patterns after 1998. Initially, only returns from completed brood years were included in the analyses. However, this resulted in the exclusion of a considerable amount of data from the post-1998 period, making it difficult to obtain sufficient data for comparison to the pre-1999 period. As a means of including these data, recoveries from incomplete broods (typically BYs 1997-2000) were assumed to have experienced the average survival rate of all completed broods for that stock, i.e. an average brood year survival index value of 1. This effectively removes the effects of brood year survival from the concentration statistic for recovery years 1999-2003. Consequently, concentration indices post-1998 could be biased high or low for many stocks, depending on whether actual brood year survival was higher or lower, respectively, than average.

Statistical Tests

Changes in the concentration index were evaluated by comparing the 1979-1998 period, except years with insufficient recoveries, to years after 1998 (1999 for the WCVI troll fishery).

Variance for p (Equation 1) is

$$\text{var}(p) = \left(\frac{1}{n-1} \right) \sum_{i=1}^n (p_{s,i,f} - \bar{p})^2 \quad (3)$$

A t-test was used to assess statistical significance of differences in the average pre-1999 and post-1998 concentration indices for each stock:

$$t_{df, \alpha=0.05(2)} = \frac{\hat{p}_{pre} - \hat{p}_{post}}{\sqrt{(SE(\hat{p}_{pre}))^2 + (SE(\hat{p}_{post}))^2}} \quad (4)$$

Results

To make this statistic more comparable between stocks, each concentration statistic value was standardized to the average value for that stock for the pre-1999 period (equation 2), represented as the 'base' in Table 10-6 and 'Pre-1999' in Tables 10-7 to 10-11. This meant that the resulting concentration index values for a stock would always average 1 for the pre-1999 period. Values greater than 1 for the post-1999 period would indicate a higher encounter rate of a stock in a fishery, while a value less than 1 would indicate a lower encounter rate, relative to this 'base' period.

Table 10-6 illustrates how brood year releases, survival and catch affect the concentration statistic. It further illustrates that when these variables co-vary, the statistic does not necessarily change. By accounting for release numbers, brood year survival, and catch levels, any changes in the concentration index can then be attributed to one or more of the following confounded factors:

1. Changes in the temporal and spatial conduct of the fishery.
2. Changes in fishery regulations, such as size limits.
3. Changes in stock distribution.
4. Changes in survival and abundance relative to other stocks.

Table 10-6: Hypothetical example of factors effecting the concentration statistic and index.

Brood year	Release	Survival	Estimated Recoveries	Total Catch	Concentration Statistic	Concentration Index
Base	200,000	0.1	200	200,000	5.0E-08	1
Yr1	400,000	0.1	800	400,000	5.0E-08	1
Yr2	50,000	0.2	100	400,000	2.5E-08	0.5
Yr3	50,000	0.2	100	200,000	5.0E-08	1

There are a number of caveats that need to be considered when attempting to assess the significance of the results presented here for any particular stock:

- It was assumed that the effects of catch, brood year survival and brood release size were linear in nature. However, this may not be true, particularly for release sizes. For example, doubling release numbers may not double the number of subsequent recoveries; limits in carrying capacity of critical rearing habitat could reduce the effectiveness of increased release numbers. Thus, recoveries may be improperly adjusted for release size for some stocks.
- It is important to recognize that for the pre-1999 period, fishery conduct may have changed significantly on several occasions. For example, there have been several temporal changes in the conduct of the WCVI troll fishery from 1979-

1998 (see Assignment #3 for details). In addition, size limits changed in 1985 and 1999 in this fishery. Both temporal and size-limit changes would be expected to affect the numbers of recoveries of some stocks in landed catch. Since the years included pre-1999 varied among stocks due to the minimum tag recovery requirement, any changes in the index specific to fishery changes would be expected to vary among stocks, depending on the years included in the analysis. Consequently, comparing changes in the index among stocks should be done with caution. While dividing the pre-1999 period into several sub-periods was considered, doing so reduced sample sizes significantly, thus reducing the power of the statistical test used. Consequently, for this analysis, the pre-1999 period was not subdivided.

- As previously stated, changes in the concentration indices may have multiple causes (the confounded factors referred to above) whose individual influences cannot be quantified.

Figures 10-8 to 10-16 illustrate the annual variability in CWT recoveries as well as the concentration indices for some stocks in the WCVI troll fishery. In some instances, as recoveries went up or down, so did the indices (e.g. Figures 10-10 and 10-16). However, for other stocks, increases or decreases in CWT recoveries did not result in a concomitant increase or decrease in the index values. This is because catches, brood year survivals or brood year releases may have concurrently changed. For example, for URBs (Figure 10-14), the index appears to be correlated with changes in CWT recoveries up to 1988. However, between 1989 and 1995, the concentration index continued to increase, even though total CWT recoveries declined. This can be explained by the fact that during these latter years, survival of contributing broods was significantly below average, while release numbers and catch levels were also low. Referring to equation 1, it can be seen how a combination of all three factors would serve to increase the concentration statistic, even if recoveries remained at the same level. This illustrates how increases or decreases in CWT recoveries alone do not necessarily reflect relative increases or decreases in encounter rates for a stock.

The fishery that exhibited the greatest changes in concentration indices amongst the stocks examined was the WCVI troll fishery (Figure 10-17), where the indices showed an increase for 16 of the 21 stocks with sufficient data (Table 10-7). The percentage change across these stocks averaged 137%. However, only four stocks showed a statistically significant increase (SKS, LRH, SPR, WSH; Figures 10-10, 10-11, 10-13, and 10-15), while two showed a significant decrease (URB, SRH; Figures 10-14 and 10-16). Of particular note was the >800% increase observed for Skagit Springs. However, it is worth noting that even such a large average increase was only significant at $p=0.04$ (Table 10-7). In fact, while the index increased for all Puget Sound stocks in this fishery, no other change in the index within this group was statistically significant. This is due at least in part to the generally high degree of variability among yearly index values (see CV values in Table 10-7) and the relatively few years of data available post-1999. Such variability was the norm rather than the exception for most stocks in all fisheries. For example, the Lyons Ferry stock showed a decrease in the index post-

1999, though this decrease was not statistically significant (Figure 10-12). Indices declined for the Robertson Cr. hatchery stock post-1999, though the decline was not statistically significant (Figure 10-9). This decline may reflect the management actions taken to reduce impacts of this fishery on WCVI stocks.

Sixteen stocks could be examined for the Georgia St. sport fishery, with all but three showing an increase in average index values (Table 10-8; Figure 10-18). Only one stock (GRN) showed a statistically significant increase. The percentage change across these stocks averaged 81% in this fishery. An equal number of the 16 stocks in the WA/OR troll fishery showed increases and decreases in the index (Table 10-9; Figure 10-19), with two stocks (NIS, SUM) showing statistically significant changes (decrease and increase, respectively). Interestingly, all but one Puget Sound stock showed a decrease in the index in this fishery. In the WA/OR troll fishery, the percentage change across the 16 stocks examined averaged 52%.

In the two northern fisheries examined, the SEAK troll fishery showed the greatest number of significant changes among the 20 stocks with sufficient data (Table 10-11; Figure 10-20). Four stocks showed a statistically significant increase (QUE, SOO, LRW, and SRH), while two showed a significant decrease (ACI and RBT). The percentage change across these stocks averaged 47%. By comparison, there were fewer significant changes observed among the 15 stocks examined for the NBC troll (Table 10-10; Figure 10-21), where indices for only two stocks (QUE, SUM) showed statistically significant changes. The percentage change across these stocks averaged 66% across the 15 stocks examined.

Considering the average absolute percentage change among all stocks, the SEAK, WA/OR and NBC troll fisheries experienced the least amount of change in indices, while the WCVI troll and GS sport fisheries experienced the most. The average absolute percentage change amongst all stocks examined was 47%, 55%, 66%, 81% and 137% for the SEAK troll, WA/OR troll, GS sport and WCVI troll fisheries respectively. Looking at the same statistic for only stocks with significant changes, the SEAK (68%), WA/OR (78%), and GS sport fisheries (76%) showed the least amount of change, while the WCVI (207%) and NBC troll (107%) fisheries showed the most. Considering the proportion of stocks in each fishery with significant differences, the SEAK and WCVI fisheries showed the largest (30% and 29% respectively, with NBC troll, GS sport, and WA/OR troll showing the least (13%, 13%, and 6%, respectively).

Comparisons across fisheries reveal some interesting trends. Increases in the concentration index were observed among Puget Sound stocks in both the WCVI troll and Georgia St. sport fisheries (Table 10-12). Conversely, indices for this stock group tended to decrease in the WA/OR troll. The indices for Upper Columbia River summers (SUM) increased in all five fisheries, significantly so in the NBC and WA/OR troll fisheries. Conversely, Lyons Ferry indices decreased in all but one fishery (NBC troll), though none of the changes were statistically significant.

Summary/Conclusions

Bearing in mind the previously mentioned cautions and caveats regarding interpretation of the concentration index data presented, some general conclusions can be drawn from this analysis. Statistically significant changes in the concentration index were observed for some stocks in 'stable' fisheries, such as the SEAK troll fishery and the Georgia St. sport fishery, suggesting that there have been significant fluctuations in stock distribution and/or relative abundances of stocks through the years. This suggests that stock dynamics can significantly change standardized encounter rates in a fishery from year to year, whether concurrent changes in fishery conduct occurred or not.

The degree of observed changes in concentration indices across a broad range of stocks intercepted in the WCVI troll fishery, suggests that changes in the conduct of this fishery have led to changes in impact on some stocks. This may be particularly true for Puget Sound stocks. However, quantifying these impacts using CWT recovery data is problematic for all of the reasons previously discussed. It is also noteworthy that impacts of this fishery on other stocks of concern, such as Snake River falls, may have decreased, as corroborated by the exploitation rate analysis data presented in Section 7.

Over all the stocks examined, the NBC troll fishery experienced a similar degree of change in indices among stocks as the SEAK troll fishery. While the more 'stable' SEAK troll fishery showed the least overall changes among all stocks examined, proportionally more stocks showed significant changes in this fishery compared to the NBC troll fishery. As mentioned above, stock dynamics may be at least partially responsible for the observed changes in concentration indices in the NBC troll fishery. However, due to the emerging nature of this analysis, these results should be viewed with caution.

Table 10-7. Concentration indices and statistics for stocks intercepted in the WCVI troll fishery. The t-test was performed on the difference between the average pre-1999 and post-1999 index values. CV=coefficient of variation. Statistically significant differences at $p < 0.05$ are indicated in bold font. See CTC (2004) for more stock specific details.

APPENDICES TO REPORT

Appendix 1. Excerpts from the CWT Panel Report.

"PSC Fishery Regimes

The 1999 PSC Chinook agreement establishes two general types of fishery regimes: (1) Aggregate Abundance Based Management (AABM); and (2) Individual Stock-Based Management (ISBM).

AABM Regimes

Major mixed stock fisheries off Southeast Alaska (all gear), Northern British Columbia (troll and sport), and West Coast Vancouver Island (WCVI troll and sport) operate under AABM regimes. These regimes are intended to: (a) adjust fishery harvest rates in response to estimated abundance of all stocks combined; and (b) reduce uncertainty for fishery management planning to meet stock-specific conservation objectives.

For AABM fisheries, abundance is indexed to stock-age population sizes through the use of an index estimated by the Chinook Technical Committee's Model. The index is derived by applying annual fishery exploitation rates for the troll component of the AABM fishery complex during a specified historical base period to two estimates of stock-age specific abundance: (a) forecasts for the coming season; and (b) observed levels during the model base period. The abundance index thus reflects the relative abundance for the coming year to that observed during the model base period when fishing patterns are consistent with those observed under the base period. The allowable fishery impact (initially landed catch, eventually changing to total mortality) is derived from a negotiated relationship between the abundance index and the allowable fishery harvest rate.

In recent years, fishing patterns in Canadian AABM fisheries have been altered in-season in response to information obtained from GSI samples in an attempt to constrain mortalities of stocks of conservation concern to Canada. Times and areas of fishing and important regulatory measures such as size limits have changed drastically from those in place during the base period. For example, during the base period, the predominant impacts from WCVI fisheries occurred in the entire area during the summer months. Recently, fishery managers have focused on reducing impacts to Chinook from WCVI and southern Strait of Georgia rivers, and interior Fraser coho. Now, the Chinook fishery predominantly operates offshore (to minimize impacts on

WCVI and Strait of Georgia Chinook)² during the October-June time period (to minimize impacts on interior Fraser coho) under reduced minimum size limit restrictions (to provide targeted marketing opportunities and reflect the smaller size of fish available during the winter-spring time frame).

While in-season management actions based on well-designed GSI methods could be usefully employed to address conservation concerns for some stocks, such measures could be fundamentally incompatible with the objectives of the 1999 PSC Chinook agreement. Unless sample sizes for GSI analysis are very large, the methods are unlikely to provide useful estimates of contributions of stocks that comprise a small proportion of the catch. These smaller stocks are often of greatest conservation concern.

Management actions in AABM fisheries which are taken in-season to reduce impacts on selected stocks raises three major concerns. First, the abundance index would no longer be appropriate to establish the allowable level of fishery impacts. For example, in the WCVI troll fishery, the stock-age specific fishery exploitation rates during the base period were estimated from coded wire tags that were predominantly collected during the summer time period that is no longer being fished. In addition, stocks that are intentionally being avoided by in-season management historically comprised a significant portion of the WCVI harvest (4%-8%) during the base period and thus affect the values of the abundance index. The technical basis for deriving the abundance index, which establishes allowable AABM fishery impacts with the objective of constraining fishery harvest rates, is undermined. Second, since fishing patterns can vary markedly from year to year, a primary purpose of the AABM regimes, to reduce uncertainty for stock-specific management planning, would be rendered meaningless. Further, instability in fishing patterns diminishes the capacity to incorporate information from catch sampling during more recent years (compared to the 1979-1982 base period) into usable estimates of exploitation rates if AABM regimes are to continue in effect in the future. Third, maintaining the same level of impact (in terms of allowable catch or mortality) while avoiding selected stocks, increases impacts on other stocks. This raises issues of "fairness" of the negotiated fishing agreements by undermining the relationship between aggregate abundance and the general objective of constraining fishery impacts on the total stock complex being exploited by the AABM fishery.

ISMB (sic) Regimes

The 1999 PSC Chinook agreement requires that fisheries that are not conducted under AABM regimes are managed to constrain total mortality, adult-equivalent harvest rates on individual natural stocks that do not meet agreed to spawning escapement goals. The 1999 Agreement calls for reductions in a harvest rate index in relation to levels observed during a specified base period. The ISBM obligation applies to the aggregate impact of all non-AABM fisheries within the individual jurisdictions of Canada and the United States on individual stocks. ISBM regimes commonly operate under domestic

² In the latest available calibration of the CTC Model (#0506), WCVI and lower Strait of Georgia stocks are estimated to comprise from 4% to 8% of the WCVI troll catch during the 1979-1982 base period.

management agreements that are designed to achieve spawning escapement and harvest allocation objectives throughout the migratory range of the stocks.

In certain circumstances (e.g., terminal area fishery management), in-season GSI information could be usefully employed in ISBM fisheries to help reduce or constrain fishery impacts on selected stocks that are not projected to meet established escapement goals. However, the difficulty of planning and conducting ISBM fisheries to meet management objectives and constraints can also be profoundly affected by substantial year-to-year variations in AABM fishing patterns that respond to in-season information. ISBM fisheries bear the brunt of uncertainty associated with the conduct of AABM fisheries since they frequently operate on maturing fish. Since spawning escapement levels are ultimately determined by the cumulative impact of AABM and ISBM fisheries, an additional burden can be placed on ISBM fishery managers to compensate for increased uncertainty in the conduct of AABM fisheries. This increased uncertainty was not anticipated when the 1999 Agreement was reached and undoubtedly will affect perceptions, which in turn are likely to increase the difficulty of negotiating agreements on future fishing regimes. Greater uncertainty in AABM fishery impacts can disrupt the capacity to successfully negotiate and prosecute management agreements that affect conservation and allocation objectives.

Further, if the ultimate result of instability in fishing patterns is increased uncertainty and the failure to attain spawning escapement goals, paragraph 9 of the 1999 PSC Chinook agreement contains provisions for adjusting both AABM and ISBM fisheries with the potential end result of an almost endless reshaping of both AABM and ISBM fisheries."

Appendix 2. CTC request for genetic data from MGL-DFO under the multi-lab sample sharing agreement

a) Request to CDFO for information concerning the DNA estimates of stock composition in the WCVI and NBC AABM fisheries in 2003-2004.

In 2004, genetics staff of the: (1) Alaska Department of Fish and Game, (2) Canada Department of Fisheries and Oceans, (3) National Marine Fisheries Service, and (4) Washington Department of Fish and Wildlife agreed to the following language and list of information for peer review and evaluation of genetic based estimates of stock composition for salmon fisheries.

Estimation of stock composition of samples taken from salmon fisheries is frequently conducted by management agencies in the Pacific Northwest and Alaska. The key outputs from the stock composition analysis are the estimated proportions of either specific populations or stocks (regional groups of populations) of interest (accuracy), and a measure of the variance associated with the estimated proportions (precision). When estimated stock compositions are produced by one agency, it is often necessary for other agencies to independently evaluate the quality of the estimated stock compositions for fisheries samples. The following list of data will allow for an independent assessment of the quality of estimated stock compositions.

1. *A list of all populations included in the baseline;*
2. *A listing of the number of individuals screened from each population by locus;*
3. *The observed allele frequencies at each locus in each baseline population;*
4. *The sample sizes for each mixture-sample analyzed;*
5. *A summary of Hardy-Weinberg equilibrium test results for each locus to identify any loci that are significantly out of equilibrium;*
6. *A summary of pair-wise tests of gametic disequilibrium to identify any locus pairs that don't appear to be independent;*
7. *The name and version of the computer program used to generate the mixed-stock analysis (MSA) estimates, as well as a listing of the program settings that were used when the MSA estimates were generated;*
8. *To the extent that alleles listed in point 3 are binned prior to the analysis, details on the binning procedures employed;*
9. *Information, if available, on population structure of the baseline populations;*
10. *Levels of accuracy and precision of estimates of stock composition for simulated mixtures as well as any known-origin mixtures analyzed, and;*
11. *Multi-locus genotypes of each individual fish analyzed from the mixed-stock sample provided in an electronic format.*

The Chinook Technical Committee (CTC) requests that the Canadian Department of Fisheries (CDFO) provide the information as described above to the CTC on or before

November 14, 2005 for the CDFO Chinook baseline used to make stock allocation estimates for the British Columbia Chinook AABM fisheries. The CTC also requests information concerning the sampling levels and procedures employed in each fishery AABM fishery by sampling time period for genetic stock composition estimates generated for the years 1985-2004.

b) Response by CDFO to CTC request for genetic data from MGL-DFO under the multi-lab sample sharing agreement, Nov 23/05.

PREFACE

This is a response to a request to provide information concerning the DNA estimates of stock composition in the Chinook AABM fisheries 2003-04. The following complies with the II points set out in the inter-lab sample sharing agreement for the exchange of information, peer review and evaluation of genetic based estimates of stock composition in salmon fisheries.

01. LIST OF POPULATIONS IN THE DFO BASELINE

The list below represents the populations, and associated sample sizes, that comprised the baseline that was used for mixed stock analysis for 2003/2004 WCVI troll samples. This baseline has been evolving as more stocks and samples are added. Consequently, the baseline used in any particular mixed stock analysis may differ slightly, depending on the year when the analysis occurred. This baseline includes populations from Southeast Alaska and to California.

The stock group names used for the DNA mixture analysis, to which these major drainage groupings map are indicated in parentheses.

02. LISTING OF NUMBER OF INDIVIDUALS SCREENED FROM EACH POPULATION BY LOCI

See attached Excel file that contains the allele frequencies by stock and microsatellite locus.

03. OBSERVED ALLELE FREQUENCIES AT EACH LOCUS IN EACH BASELINE POPULATION

See attached Excel file that contains the allele frequencies by stock and microsatellite locus. Also see Spam format baseline file Chinookcoastwide.bse

04. SAMPLE SIZES FOR EACH MIXTURE ANALYSIS

Sample sizes vary with each study. For the 2003/2004 WCVI troll sampling project, a total of 1400 samples were analysed spanning the period Oct/03-Sept/04. See multi-locus genotypes of each fish within this sample group (item #11).

05. SUMMARY OF HARDY-WEINBERG EQUILIBRIUM

Table 1 summarizes the results of Hardy-Weinberg equilibrium tests of the 13 microsatellite loci used for stock differentiation. This test was performed using a representative sample of 52 Chinook salmon spawning populations in the Fraser River drainage.

Table 1. Number of alleles, expected heterozygosity (H_e), observed heterozygosity (H_o), percent significant Hardy-Weinberg equilibrium tests (HWE, $N=106$ tests), and F_{ST} among 52 Chinook salmon spawning locations (standard deviation in parentheses) for 13 microsatellite loci.

Locus	Alleles	H_e	H_o	HWE	F_{ST}

06. PAIR WISE TEST OF GAMETIC DISEQUILIBRIUM

Results

There was no evidence of linkage between any of the microsatellite loci used in this study, but four of the 52 samples surveyed in the study exhibited significant linkage disequilibrium in more than 10% of the pairwise comparisons between loci (Table 1). These sample locations were Harrison River, Tete Jaune, Fontoniko, and Bessette Creek.

Discussion

Significant linkage disequilibrium was detected in samples from four populations: Harrison River, Tete Jaune (main stem Fraser River), Fontoniko Creek, and Bessette Creek. Linkage disequilibrium may reflect sample admixture (Waples and Smouse, 1990) in the Harrison River and Tete Jaune samples. The Harrison River samples were obtained from broodstock collections at a hatchery on the Chehalis River, a tributary of the Harrison River. Initial broodstock for the hatchery was derived from Chinook salmon collected from the Harrison River, and over time broodstock has been developed from fish returning to the hatchery. Chinook salmon returning to the Chehalis hatchery were also used to found the Chilliwack River population that is maintained by production in the Chilliwack hatchery and spawning in the Chilliwack River. During the 1990s, Chinook salmon were transplanted back from the Chilliwack hatchery to the Chehalis hatchery. Thus, the samples examined in our study, collected between 1988 and 1994, may reflect some mixing of genetically related but heterogeneous groups of fish from the Harrison, Chehalis, and Chilliwack rivers in the Chehalis hatchery broodstock. The Tete Jaune samples were obtained at Tete Jaune Cache in the extreme headwaters of the Fraser River. As the samples were collected from the mainstem Fraser River, there is potential for admixture of populations, although it is thought that there are few Chinook salmon spawning sites upstream from this location. Significant linkage disequilibrium was detected in single-year samples from Fontoniko Creek (a tributary of the McGregor River) and Bessette Creek (a tributary of the Shuswap River). Population admixtures would not typically be expected in such terminal locations, and the cause of

the disequilibrium is unknown. The disequilibrium observed in the Bessette Creek sample may simply reflect small sample size (17 fish).

07. NAME AND VERSION OF COMPUTER PROGRAM.

The program used for stock allocation is based on a Bayesian approach to mixture analysis developed by Pella and Masuda (2001). The algorithms were rewritten in Cplus in a program referred to as Cbayes (Neaves et al. 2005)

Neaves, P. I., C. G. Wallace, J. R. Candy, and T. D. Beacham. 2005. CBayes: Computer program for mixed stock analysis of allelic data. Version 2.2.1. Free program distributed by the authors over the internet from http://www.pac.dfo-mpo.gc.ca/sci/mgl/data_e.htm

Pella, J., and M. Masuda. 2001. Bayesian methods for analysis of stock mixtures from genetic characters. Fishery Bulletin 99: 151-167. Free program distributed by the authors over the internet from <ftp://www.wabl.afsc.noaa.gov/sida/mixture-analysis/Bayes/>

Below are typical settings from the Cbayes control file used for the analysis of this data.

10. LEVEL OF ACCURACY AND PRECISION OF ESTIMATES.

Below is a test of the accuracy of stock allocations using the DFO 13 loci baseline on samples of known origin (via CWTs) collected in Canadian fisheries (Figure 1 and 2).

Figure 1. Estimated percentage stock compositions of a sample of 306 Chinook salmon marked with coded wire tags and sampled from fisheries in British Columbia during 1997. The baseline used for the stock composition analysis consisted of approximately 52,000 Chinook salmon surveyed for variation at 13 microsatellite loci from 325 populations across the Pacific Rim distribution of the species. Actual percentages are in white, and estimated percentages, with standard deviations, are in black. (From Beacham et al. 2006 in review).

Figure 2. Estimated percentage stock compositions of a sample of 297 Chinook salmon marked with coded wire tags and sampled from a troll fishery off the southwest coast of Vancouver Island during 2001 (From Beacham et al. 2006 in review).

11. MULTI-LOCUS GENOTYPES FOR EACH FISH ANALYZED IN MIXTURE.

The multi-locus genotypes for mixed stock fisheries samples in genepop format for Chinook caught in the WCVI troll fishery from October 2003-September 2004 are available upon request.
